per cent relative humidity, although, at this latter humidity, in only one series were a few immature cleistothecia formed. The range in *M. nitida* was from 100 to 29.5 per cent, at which latter point a few cleistothecia were formed in one series of cultures. In view of the previous experiments in which growth at low humidity did not take place, it seemed desirable to determine whether or not variations in the amount or depth of agar in the Petri dishes would explain this variation in behavior. Accordingly, in a subsequent series, in which less agar per Petri dish was used, it was found that the agar dried out at both 49.0 and 29.5 per cent relative humidities and as a result no cleistothecia were formed, nor was there any visible growth. Since in neither series did *M. brachytricha* produce any cleistothecia at 29.5 per cent relative humidity, the range for the production of cleistothecia in *M. nitida* would seem to be a little wider than that in *M. brachytricha*. For both species, the optimum of the relative humidities used was 91.2 per cent, which, it will be recalled, is also the optimum for growth and for conidium formation.

Although a humidity of 91.2 per cent seemed to be the optimum for both conidium and cleistothecium production in the two species of *Magnusia*, such a high humidity has not been universally found necessary for the optimum development of the reproductive bodies. Robinson (1926), for example, found that the sexual reproduction of *Pyronema confluens* was best at humidities ranging from 68.5 to 52.0 per cent, but Reidemeister, cited in Hall (1933), found that high humidity favored conidium formation in *Botrytis cinerea*, and Coons (1916) found that moisture had an inhibiting effect upon pycnidium formation of *Plenodomus fuscomaculans*.

At humidities below 91.2 per cent the amount of agar medium per Petri dish undoubtedly plays an important part in the percentage of cleistothecium formation obtained, for the greater the amount of agar, the greater is the amount of moisture from the agar available to the fungi. In effect, there are two factors to be considered in the humidity experiments: the moisture content of the air and the availability of moisture in the substrate. It is possible to control in some measure only the former. At the lower humidities there is, of course, a constant loss of water from the substrate. As already pointed out, if moisture is available in the substrate, cleistothecia will be produced at lower humidities than if it is not available. Below a certain critical point there seems not to be sufficient moisture in the medium to make up for the lack of moisture in the air.

Other investigators are agreed that growth and reproduction occur best at fairly high relative humidities. Fisher (1939), for example, found that the sooty moulds grew best at 100 and 99 per cent relative humidity, with the lower limits of growth at 92.5 per cent. McCrea (1931) found that abundant moisture was needed for the growth of *Claviceps purpurea*. Walter, cited by Tomkins (1929), found that *Penicillium* grew independently of the relative humidity down to 95 per cent, and that *Aspergillus*

glauca grew at a lower relative humidity than *Penicillium glaucum*, although there was no growth below a relative humidity of 85.0. Although the same criticism can be made of the *Magnusia* experiments that apply to Walter's (1924) work, namely, that the temperature of the experiments was not constant, and that moisture present in the drop had to come into equilibrium with the air, it should be kept in mind that in nature a perfectly constant temperature is not to be expected, and an interchange of moisture between the substrate and the surrounding atmosphere would be of normal occurrence. Under laboratory conditions, in the enclosure of the desiccator, a relatively constant equilibrium would be reached which would not obtain in nature, where a fairly free circulation of air or moisture drawn from soil may make the equilibrium reversible.

During the course of these investigations, attention was paid to the occurrence of sector mutants in cultures subjected to varied environmental factors, in the hope that some light might be thrown on factors causing this phenomenon. In several of the plates at 70.4 per cent relative humidity and above, sector mutants occurred, most of which were composed of sterile white mycelium. The one exception was *M. brachytricha* at a relative humidity of 80.6, which had a dark sector composed of black mycelium growing in the agar; none of the mycelium was aerial. The sector was isolated and has remained true in culture to the original black type for over three years. Since sector mutants arose in all colonies in which there was rapid vegetative growth, it would seem that they did not arise as a result of unfavorable environmental conditions but that the cause for their appearance must be sought either in the nature of the medium or in the behavior of the nuclei in a thallus that has resulted from rapid vegetative growth with the accompanying repeated nuclear divisions. As a result of aberrant nuclear division it is possible that genetic characters were not divided equally between the daughter nuclei so that when the nuclei with atypical genetic structure became segregated in a branch of the mycelium, this branch gave rise to the so-called mutant.

SUMMARY

The effect of humidity on conidial germination, on growth and reproduction of the two species of *Magnusia* may be summarized as follows:

The range of humidity in which conidial germination took place was somewhat wider for *M. nitida* than for *M. brachytricha*—from 100 through 95.6 per cent relative humidity for *M. nitida*, and from 100 through 97.5 per cent for *M. brachytricha*, with an optimum for both species at 99.5 per cent relative humidity.

The conidia of *M. nitida* made a better recovery from drying than did those of *M. brachytricha*.

There was no difference in the range for growth of the two species, since both were able to persist in the full range of relative humidities from 29.5 to 100 per cent, with an optimum for both species at about 91.2 per cent relative humidity.

The range for the production of conidia in both species was from 100 to 60.7 per cent relative humidity, with most conidia being produced at a relative humidity of 91.2 per cent.

There was a difference in the range for the production of cleistothecia in the two species: the range in *M. nitida* was from 100 through 29.5 per cent, and that in *M. brachytricha* was from 100 through 49.0 per cent, with an optimum production at 91.2 per cent, which is the optimum for growth and for the formation of conidia.

Sector mutants occurred in several of the plates at 70.4 per cent relative humidity and above, the most noteworthy of which occurred in cultures of *M. brachytricha* at 80.6 per cent relative humidity—a black mycelium which has continued true to type for over three years. Humidity, however, is not thought to be the deciding factor in the production of sector mutants, excepting that a high humidity favors rapid vegetative growth.

THE OCCURRENCE AND TYPES OF VESSELS IN THE VARIOUS ORGANS OF THE PLANT IN THE MONOCOTYLEDONEAE¹

Vernon I. Cheadle

APPARENTLY NO broad survey has been made to ascertain either the occurrence or the types of vessels present in the Monocotyledoneae. Indeed, the only paper of any real importance in this respect is one by Caspary published in 1862. The publications of Schulze (1893), Bädcker (1903), Bernatsky (1904, 1906), and Fuchsig (1911) also seem to report vessels authoritatively. Numerous publications have appeared in which the general topography of the vascular tissues in many groups of plants has been discussed, but in which only incidental observations concerning the true nature of the tracheary elements have been recorded. Papers of this nature, to mention only a few, are those by Scharf (1892), Colozza (1898, 1901), Plowman (1906), Chrysler (1906, 1907), Zweigelt (1913), and Bouvier (1915). Furthermore, the loose use of the words *Gefasse*, *vaisseau* and *vessels* by many writers has led to great confusion regarding the meaning of the term "vessel." These words have often been employed indiscriminately in describing tracheary elements, without any apparent attempt to determine the actual structure of such elements. Consequently, the observations recorded in the literature are often untrustworthy. In their review of the comparative anatomy of the Monocotyledoneae, however, Solender and Meyer (1928, 1929, 1930, 1933) draw a clear distinction between tracheids and vessels, but the information in this important series of publications is fragmentary. Generalizations concerning the occurrence and types of vessels in the Monocots, such as those made by Jeffrey (1917), are also apparently based on an unrepresentative section of the plants in this group of the angiosperms.

It is obvious from the foregoing that the present paper is a report on the occurrence and types of true vessels in the various organs from a wide representation of the Monocots. Other papers to follow will discuss a number of features of vessels, and will attempt to point out the lines of specialization these elements exhibit in this group of plants. The impressive evolutionary document developed from a consideration of the variations in tracheids and vessels in other groups of plants has assumed an increasingly important part in phylogenetic studies (see papers by Heimsch and Wetmore, 1939; Tippe,

1938; and Vestal, 1937). A study of these elements from the same viewpoint in the Monocots may very well produce results of importance along similar lines. Furthermore, an analysis of the data accumulated from all parts of the plant in genera and species from extremely diverse habitats has great possibilities for an *expansion* of, and a *check* on, the evidence concerning (1) the phylogenetic importance and (2) the physiological significance of the structural differences in tracheary elements.

A preliminary report (Cheadle, 1939) on this subject has been presented, at which time about one-third of the species now available were considered.

MATERIALS AND METHODS.—About 325 species of 220 genera in 41 families as defined by Hutchinson (1934) were investigated in the present study.² The names of the families are listed throughout the paper, and representative genera and sometimes species are noted under these families. Wherever possible, all parts of the plant were examined by the utilization of both sectioned and macerated tissues. Practically all tissues were macerated, but many of them have not yet been sectioned. The sections were made from materials embedded either in paraffin or in celloidin, following in general the techniques suggested respectively by Zirkle (1930) and Wetmore (1932). Materials of the Palmae and plants of similar construction generally need prolonged treatment with hydrofluoric acid and very gradual infiltration with celloidin. The method of preparing tissues for separation of the cells was based upon a variation of the Jeffrey method (Chamberlain, 1932). This variation includes the use of a constant temperature (55-60°C.) oven and a method for preventing the corks from blowing out of the bottles in which the material is placed during the maceration procedure. The clamps illustrated by Wetmore (1932) were used for this purpose. Experience alone dictates not only the percentage of chromic and nitric acids to be used with different materials but also the length

² The author gladly expresses appreciation to Professors I. W. Bailey and R. H. Wetmore for materials from the Harvard Collection, to Harvard University for supplying the means of personally collecting in Cuba, to Drs. E. S. Barghoorn and C. Heimsch and to R. A. Howard for collections in Cuba, to Miss N. B. Whitford for collections in New York, and to Miss D. Rounds for collections in New Mexico. Much of the material, especially of the Gramineae, Cyperaceae and Juncaceae, was collected in Rhode Island. A few plants were gratefully received from the Greenhouse at Rhode Island State College.

¹ Received for publication January 24, 1942.

With the support of a grant from the American Philosophical Society, and a grant from the American Academy of Arts and Sciences.

of time necessary to keep the materials in the oven. A fair average for the materials treated would be the use of equal portions of 5 per cent nitric and 5 per cent chromic acids for a period of about twelve hours. Separation of the tracheary cells in a majority of tissues in the Monocots is difficult for two reasons. First, only a small number of vascular elements can be obtained from large pieces of material. Secondly, the walls of the elements are often too thin to withstand shaking about in a test tube, and the vascular elements are often surrounded by fibers. Therefore, the tissues must merely be softened in the maceration fluid and then later, after thorough washing, they must be teased out carefully on a slide. These separated cells, still on the slide, were stained in safranin, dehydrated, and finally mounted in diaphane.

Some organs were also injected with diluted black India ink to check observations made on macerated and sectioned tissues. The organs to be injected

were washed thoroughly in running water and pumped free of air. The diluted ink was placed in a 50 cc. burette, at the bottom of which was attached a piece of rubber tubing of proper diameter. The tubing was shut off by a screw clamp while the material was inserted. This insertion was carried out under water to prevent the introduction of air bubbles. The screw clamp was then loosened and the ink allowed to flow into the material. When viewed against a white background, the ink, if vessels were present, could be seen streaming into the water from the vascular bundles. The material was taken out after a period of fifteen or twenty minutes and then macerated as pointed out in the preceding paragraph. The presence of carbon in a linear succession of tracheary elements was considered as proof that vessels are present, even if the ink could not be observed streaming from the vascular bundles during the ink injection process. These injections were

Fig. 1-10.—Fig. 1. *Butomus umbellatus* (Butomaceae), showing a pole of the xylem of root at left in cross section, and parts of vessels at right with perforation plates. The cross section of the large vessel was taken at the end of a vessel element, hence the apparent side wall is actually the perforation rim. The letters indicate the positions of the various vessels in the xylem pole. The last-matured metaxylem is at A, the earliest at C. $\times 500$.—Fig. 2. *Hymenocallis caribaea* (Amaryllidaceae), showing reticulate perforation plate of a vessel taken from center of the root. $\times 400$.—Fig. 3. *Cooperia pedunculata* (Amaryllidaceae), reticulate perforation plate of a vessel from center of root, a type rather common in the Amaryllidaceae. $\times 400$.—Fig. 4. *Dimerocostus uniflorus* (Zingiberaceae), portion of a tracheid from the stem, with an end wall which simulates a perforation plate. Tracheids in *Strelitzia* (Strelitziaceae) are similar. $\times 240$.—Fig. 5. *Carex intumescens* (Cyperaceae), parts of two annular tracheids where their ends overlap, taken from the stem. $\times 425$.—Fig. 6. *Phoenix dactylifera* (Palmae), a scalariform perforation plate taken from the stem. $\times 140$.—Fig. 7, 8, 9, 10, all from the stem of *Rhoeo discolor* (Commelinaceae). Fig. 7 is a spiral vessel with porous perforation plate, 8 is a spiral vessel with scalariform plate, 9 is an annular vessel with porous perforation plate, and 10 is an annular vessel with a reticulate perforation plate. All $\times 290$.

always repeated at least twice, and often more than three or four times in questionable cases.

Except for part of figure 1, the drawings were made freehand from macerated tissues.

OBSERVATIONS AND DISCUSSION.—Before proceeding to a discussion of the data, it should be emphasized that the final data used for this paper were often based on material from several plants or from several similar organs of the same plant. For example, several roots (adventitious) from a single grass plant, or several roots obtained from different specimens, were observed in ascertaining the true picture of the tracheary elements in a single species. Furthermore, in the stems of palms (and plants of similar structure), materials were examined from both the central and the peripheral regions at several levels, including areas near the ground level and near the crown of leaves. Various parts of the rachis in large palm leaves, as well as various parts of spreading inflorescence systems, received comparable attention. Similarly, whenever roots of small and large diameter were present in the same plant both were treated. In other words, an attempt was made wherever possible to obtain a representative sampling of the organs, whatever their size might be. This type of sampling, although it involves a large amount of routine work, has led to the conclusion that the variations that occur between different areas of any particular organ of a species, such as the stem of a palm, are so small as to be entirely negligible in a survey of this particular nature.

The discussion of the data has been divided so that it includes (1) families whose members have no vessels and have little or no thickening of the xylem elements, (2) families whose members have vessels only in the roots, (3) families which have both (a) members with vessels only in the roots and (b) members with vessels in the roots and also in some other organs of the plant, and (4) families with vessels throughout the plant. The investigation is primarily concerned with metaxylem elements, but wherever the protoxylem is not specifically mentioned, no protoxylem vessels were definitely identified. It is more than probable that, where both metaxylem and protoxylem are clearly present and vessels do not occur in the metaxylem, they are also absent from the protoxylem. This comment above is a preliminary statement on a definite problem which will be considered in a later paper. Environmental influences will also be considered in subsequent publications, although they will be more or less casually treated in a few of the families included in this paper.

The figures in the tables presented in this paper are based upon species rather than genera, because there is no evidence available at this time to show that all the species of a genus are anatomically similar with regard to the types of vessels present. As a matter of fact, in those genera in which several species have been examined, the species more often than not were found to vary among themselves. Within certain single genera in the grasses and sedges there is as great a variety of types of vessels as can be dis-

covered throughout the entire family. In only three cases were more than five species in any genus considered and the greatest number for any genus was eight.

The vessel will be discussed generally only in terms of the type of perforation plate which occurs on the vessel members. The term perforation plate and its variations used here (usually scalariform and simple or porous [Fig. 1, B and C]) are used in the sense in which they were defined by the Committee on Nomenclature of the International Association of Wood Anatomists (1933). The terms protoxylem and metaxylem are used as they are defined by Eames and MacDaniels (1925). The meaning of the terms early-formed (or matured) and later-formed metaxylem is indicated in figure 1 (and its legend).

Families whose members have no vessels and have little or no thickening in the xylem elements.—Hydrocharitaceae: *Elodea canadensis* Michx., *Vallesneria spiralis* L.; Lemnaceae: *Lemna perpusilla* Torr., *Spirodela polyrhiza* (L.) Scheid.; Najadaceae: *Najas flexilis* (Willd.) Rostk. & Schmidt., *N. flexilis* var. *robusta* Morong., *N. gracillima* (A. Br.) Magnus; Ruppiaceae: *Ruppia maritima* L.; Zannichelliaceae: *Zannichellia palustris* L.; Zosteraceae: *Zostera marina* L. All these families are in general composed of aquatics. In *Elodea* of the Hydrocharitaceae, annular to spiral tracheids occur in the nodes of the stems. In *Spirodela* of the Lemnaceae, annular tracheids are present in the roots and leaves. No vascular elements with even annular thickenings were found anywhere in the plant in the remainder of the species examined in this study, although Chrysler (1906) reported that "xylem" occurs in the nodes of the creeping stem of *Zostera* and that annular to spiral tracheids occur in the nodes of *Ruppia*, *Zannichellia*, and in *Najas flexilis*. The differences in observations may be due either to difference in age of the materials or to variability in the specimens themselves. At any rate, there appears to be no question concerning the absence of vessels.

Families with vessels in the roots only.—Table 1 includes a representation of the material discussed in this section.

Agavaceae: nine genera, twenty-four species, including *Agave*, *Cordyline*, *Dracaena*, *Nolina*, *Yucca*, etc. In all but eight species, only vessels with simple (porous) perforation plates were observed. In four species, a few scalariform plates were found in the early-formed metaxylem, while in one the scalariform and simple plates were more or less evenly divided. In three species, only scalariform plates are present. The dominant type of perforation is obviously the simple form. Vessels with scalariform plates were found in the leaves of *Cordyline* and *Dracaena*. Ink injections confirmed observations made of macerated and sectioned materials. Similar treatment of the stems in those genera indicated complete absence of vessels; the tracheids have scalariformly pitted end walls.

Alismataceae: *Sagittaria*, with four species and one forma. Simple perforations are the rule, with a

TABLE 1. Families having vessels in roots only. The variations in types of perforation plates and the number of species in which each type occurs.

Family	Total no. spp.	Perforation plates				
		Porous only	Porous and scanty sca- lariform	Porous and scalariform	Scalariform and scanty porous	Scalariform only
Agavaceae	24	17	4	1	0	2
Alismataceae	4	1	2	1	0	0
Alstroemeriaceae	1	1	0	0	0	0
Amaryllidaceae	20	1	1	0	0	18
Araceae	8	0	0	0	0	8
Butomaceae	2	0	1	1	0	0
Cannaceae	1	0	1	0	0	0
Hypoxidaceae	1	0	0	0	0	1
Juncaginaceae	1	0	0	0	0	1
Pontederiaceae	3	0	0	0	0	3
Potamogetonaceae	5	0	0	0	0	5
Scheuchzeriaceae	1	0	0	0	0	1
Strelitziaceae	3	0	0	0	0	3
Trilliaceae	3	0	0	0	0	3

few scalariform plates in the early-matured metaxylem. The stems of *Sagittaria* have tracheids with scalariformly pitted end walls, and the membranes remain in the pits.

Alstroemeriaceae: *Alstroemeria aurantiaca* D. Don. Only simple plates occur in the roots. The metaxylem of the stem has tracheids with scalariformly pitted, long oblique end walls.

Amaryllidaceae: fifteen genera, twenty species, including *Amaryllis*, *Clivia*, *Cooperia*, *Crinum*, *Narcissus*, etc. Scalariform plates with variations to reticulate (fig. 2 and 3) were found in fourteen genera and eighteen species. There are a few scalariform plates in the early-matured metaxylem in *Allium*, but the remainder of the vessels have simple plates. There is no question about the absence of vessels in the remainder of the plant, and the tracheids seldom have heavily thickened walls. These tracheids are usually reticulately thickened, or have thickenings so laid down as to leave conspicuous scalariform pits.

Araceae: seven genera, eight species, including *Acorus Calamus* L. and *Arisaema triphyllum* (L.) Schott. All these species have scalariform perforation plates. The stems of several (including *Acorus Calamus* L.) were injected with India ink to confirm the absence of vessels. The tracheids are often of large diameter and great length, and generally have scalariformly pitted side and end walls. The corm of *Arisaema* has numerous oval-pitted tracheids.

Butomaceae: *Butomus* and *Hydrocleis* with two species. In *Butomus* there are a few scalariform plates in the small (fig. 1, B and C) early-formed metaxylem, while in the remainder (fig. 1, A and B) the vessels have simple plates. In *Hydrocleis*, both scalariform and simple plates are found in the later-formed metaxylem, but scalariform alone occur in the early metaxylem. The tracheids in the remainder

of the plant are often similar to the vessel members, but membranes are present in the scalariform pits of the end walls.

Cannaceae: *Canna indica* L. The vessels have both porous and scalariform plates, the former occurring almost entirely in the early-formed metaxylem. The pitting in the tracheids of the rhizome and aerial stem is similar to that of the vessels in the roots, and the end walls of successive tracheids are arranged so as to resemble perforation plates. Although it is possible that some perforations actually may be present in these end walls, none was discovered.

Hypoxidaceae: *Hypoxis hirsuta* (L.) Coville. The roots have scalariform plates in the vessels. The length of some of these plates is not more than twice the diameter of the vessels. Scalariformly pitted tracheids are found in the corm and inflorescence axis. There are clearly no vessels in the shoot system in the material observed.

Juncaginaceae: *Triglochin maritima* L. This plant, collected along the coastal flats, has very long scalariform plates in the vessels of the roots. No vessels occur elsewhere, although scalariformly pitted tracheids (irregular in shape in the rhizome) are present throughout the plant.

Pontederiaceae: *Pontederia* and *Eichornia* with three species. Only scalariform plates occur in the roots. The stems of *Eichornia crassipes* Solms have elements whose end walls are very similar to scalariform perforation plates.

Potamogetonaceae: *Potamogeton* with five species. Clear perforation plates of rather short length were seen at least in the larger vessels of the roots. Vascular elements in the shoot system are in general merely protoxylic in nature and are clearly not vessels. Those metaxylic elements which occur are scalariformly pitted and are without doubt tracheids.

Scheuchzeriaceae: *Scheuchzeria palustris* L. Long scalariform plates (the pit membranes may, how-

ever, remain undissolved in some cases) occur at least in the last-matured metaxylem of the roots, and very long tracheids appear in the remainder of the plant. The latter elements are not strongly thickened and the end walls sometimes have the appearance of perforation plates.

Strelitziaceae: *Heliconia*, *Ravanelia*, *Strelitzia*, with three species. Only scalariform plates occur in the roots. Large protoxylem elements generally occur in the shoot, and these annular to spiral elements have long end walls. That is, these cells gradually taper down to very small diameters. In the inflorescence axis of *Strelitzia*, the spiral elements are often characterized by shorter, but obliquely placed, end walls whose bars of thickening are somewhat smaller than those of the remainder of the element (fig. 4). Ink injections, however, indicated that vessels are absent. A few metaxylem tracheids, smaller in diameter, are also present in the shoot system, although the leaves generally lack them.

Trilliaceae: *Trillium* and *Medeola*, with three species. The scalariform plates in the roots find no counterparts in the remainder of the plant. Metaxylem elements are generally scalariformly pitted and have no end walls suggestive of perforation plates.

Families which have both (a) members with vessels only in the roots and (b) members with vessels in roots and also in some other organs of the plant.—Table 2 gives a representation of the material discussed in this section. Since the tabular presentation of the data from all parts of the plant in this particular category of families is somewhat difficult, only the roots, stems, and leaves are included. If the inflorescence axis is the only real aerial stem structure, as is true in *Musa*, it is included as a stem. Where vessels occur in other organs in the plant, they are mentioned in the treatment of the separate families.

Bromeliaceae: six genera, eight species, including *Billbergia*, *Dyckia*, *Tillandsia*, etc. Only scalariform plates occur in the roots of the four species studied. The material available from the shoot system was not complete enough to make an adequate comparison between the xylem of the roots and the shoots. Furthermore, the elements in most of the plants examined are small in diameter and, therefore, difficult to work with. In only one of the stems of the six species observed are vessels clearly absent. In the remaining five, vessels are questionably present. At least the end walls of the elements are significantly different from the side walls in pitting, and probably some pit membranes are lost to form perforation plates of the scalariform type. Of the leaves examined in four species, three clearly have no vessels, while in one scalariform plates without doubt occur. This family seems, therefore, to have either very primitive perforation plates in both the stems and roots, or merely in the roots.

Iridaceae: *Gladiolus*, *Iris* and *Sisyrinchium*, with five species. In the roots of all these species the prevailing type of perforation plate is the simple form. In all of the roots, however, a few scalariform plates

occur in the early-matured metaxylem. No vessels occur in the shoot system of *Iris* and *Gladiolus*, and the tracheids are reticulately or scalariformly thickened throughout. In *Sisyrinchium angustifolium* Mill., however, scalariform plates are found throughout the shoot system. These occur in the metaxylem, and are usually limited to the larger elements. There may be, of course, other plants with vessels throughout in this family.

Liliaceae: thirty-one genera, forty-three species, including *Aloe*, *Asparagus*, *Clintonia*, *Colchicum*, *Convallaria*, *Lilium*, *Polygonatum*, etc. There is considerable variation in this family, both with regard to the presence or absence of vessels and to the type of perforation plates in those vessels which are present. The roots of this family generally have scalariform plates in the vessels, but *Aloe*, *Anthericum*, *Asparagus*, *Chlorophytum*, *Kniphofia*, *Liriope*, *Ornithogalum*, *Paradisea*, and *Smilacina* generally have porous plates, with a few scalariform plates in the early-matured metaxylem in some cases. The remainder of the total number noted in table 2 under the column of both porous and scalariform have only porous plates in the metaxylem which is the very last to mature. Only in *Chlorophytum elatum* R. Br. do vessels occur throughout the plant, with scalariform plates in the stems and leaves. *Asphodelus* also has vessels in the stems, but no leaves were available for study. In *Asparagus*, scalariform plates are present in the metaxylem of the aerial stems, but vessels are absent in the rhizomes and in the modified stems which serve as leaves. Vessels with scalariform plates occur in the aerial stems of *Polygonatum commutatum* (R. & S.) Dietr., but are absent elsewhere in the shoot system. Ink injections confirm this statement. Ink injections were also made of the stems and rhizomes of *Clintonia*, *Convallaria*, *Lilium*, *Smilacina*, and *Uvularia* to confirm the absence of vessels in these organs. The tracheids in the plants just mentioned are long, but have end walls which to a certain extent simulate perforation plates. However, membranes are apparently present in the pits of the scalariformly thickened end walls in these tracheids. At best, the material investigated indicates that vessels seldom occur in stems of these genera. In the great bulk of the Liliaceae there are no vessels in the shoot system, although there are vessels of some type in all of the roots.

Marantaceae: *Calathea*, *Maranta*, *Thalia*, with four species. Aside from *Maranta leuconeura* Morr., no complete plants were available. Scalariform plates were found in the roots and rhizomes of this species but not elsewhere in the plant. No vessels occur in the stems of *Calathea*. In *Thalia*, spiral and scalariform elements of the stems and leaves have long obliquely placed end walls whose bars of thickening are narrower than those of the side walls. Some of these, at least, are probably vessels, although not enough material was available to confirm this conclusion by the use of ink injections.

Musaceae: *Musa paradisiaca* L. and *M. paradisiaca* var. *sapientum* Kuntze. Vessels in the roots

TABLE 2. Families with both (1) members with vessels in roots only and (2) members with vessels also in some other organ of plant. Indicating presence or absence of vessels, the type of perforation plates, and number of species in which each occurs.

Family	Total spp. ^a	Perforation plates in roots			Occurrence of vessels		
		Porous only	Scalariform and porous	Scalariform only	In stems ^b	In stem and ^b leaf of same species	In roots only
Bromeliaceae	8	0	0	4	5? in 6	1 in 4	1 in 2 ^d
Iridaceae	5	0	5	0	1 in 5	1 in 5	4 in 5
Liliaceae	43	5	14	23	7 in 41	1 in 41	35 in 41
Marantaceae	4	0	0	1	1 in 4	0 in 3	0 in 1
Musaceae	2	0	1	0	1 in 1	0 in 1	0 in 1
Orchidaceae	20	0	1	3	5 in 16	1 in 9	3 in 4
Ruscaceae	2	0	0	1	1 in 2	0 in 1	1 in 1
Sparganiaceae	5	0	0	3	3? in 3	3 in 3	0 in 3
Zingiberaceae	14	0	0	4	7? in 10	4 in 8	3 in 3

^a Since not all organs of the plant in all species were available, the total species merely indicates the total in which at least one organ was available.

^b Only scalariform plates occur in these organs.

^c The question mark indicates that vessels are questionably present.

^d The totals in this column are usually low because the roots, stems, and leaves of any species must be available in order to construct the column.

have simple plates in later-matured metaxylem and scalariform plates generally in the early-matured metaxylem. Scalariform plates seem to occur in the inflorescence axes but apparently nowhere else in the shoot system. The larger elements in the xylem are the vessels and these have scalariformly pitted side walls which are weakly thickened. Only spiral and annular tracheids occur in the leaves studied.

Orchidaceae: fifteen genera, twenty species, including *Calopogon*, *Cattleya*, *Cypripedium*, *Dendrobium*, *Vanilla*, etc. Only scalariform plates are found in the roots of three of the four species studied, and a few simple plates occur with the scalariform ones in the remaining species. This family apparently has considerable variation with respect to the presence or absence of vessels in the shoot system. The larger elements of the metaxylem of the stems in five spe-

cies, especially in *Vanilla*, are undoubtedly vessels with scalariform plates. Vessels questionably occur also in two other species. In *Calopogon*, *Cypripedium*, *Dendrobium*, *Habenaria*, and *Renanthera* vessels are definitely absent in the stems (and inflorescence axes). Vessels with scalariform plates occur in the leaves of *Epidendrum* and *Scaphyglottis*, but could not be identified with any degree of certainty in the leaves of other species. The tracheids in this family are numerous in each bundle and generally have considerable wall thickening, although spiral and annular forms also occur in all cases. Further material of this large family is needed to ascertain the degree of variation in the occurrence and specialization of vessels.

Ruscaceae: *Ruscus aculeatus* L. and *Danae racemosa* Moench. *Ruscus* has scalariform plates in the

^a The question mark indicates that vessels are questionably present.

roots and there are no vessels elsewhere in the plant. *Danae* has scalariform plates in the stems, but no further organs of this plant were available for study. The large vessels of *Danae* are quite in contrast to the very small and numerous tracheids of *Ruscus*.

Sparganiaceae: *Sparganium*, with five species. Well-defined scalariform plates occur in the vessels of the roots. In forms like *S. lucidulum* Fernald & Eames, vessels with long scalariform plates are clearly present throughout the plant. In *S. fluctuans* (Morong.) Robinson, vessels are absent in the rhizome. Scalariform plates are probably present in all other species and organs, although they are not so clearly defined as in *S. lucidulum*.

Zingiberaceae: nine genera, fourteen species, including *Alpinia*, *Amomum*, *Costus*, *Hedychium*, *Languas*, etc. The roots of the four species available all have scalariform plates. In seven of the ten species in which aerial stems (or inflorescence axes) were available, vessels with long scalariform plates are probably present. These elements do not have such sharply outlined plates as occur in the roots, but they are significantly different from the side walls. In three species, vessels are definitely absent in the stems. The leaves in five of the nine species have no vessels, while the remaining four have long scalariform plates similar to those in the stems. The tracheids and vessels in this family are generally thin-walled and often have spiral thickening (fig. 4) with an occasional connecting bar across the spiral. The conducting elements are, therefore, difficult to macerate successfully. There seems to be little doubt that this family has (1) species with vessel-less shoot systems, as well as (2) species with vessels throughout the plant, and (3) species with vessels in the root and stem only.

Families with vessels throughout the plant.—Table 3 does not indicate the relative number of porous and scalariform plates under the column "porous and scalariform". The data were originally charted to indicate "porous and scanty scalariform" and "scalariform and scanty porous", in addition to

the columns indicated in the table. This analysis of the data will be given for those families in which such a treatment seems pertinent.

Commelinaceae: *Commelina*, *Rhoeo*, *Tradescantia*, *Zebrina*, with five species. The roots of these species all have porous plates in addition to a few scalariform plates in the early-matured metaxylem. In the aerial stems, the porous and scalariform plates occur in about equal numbers in three species while in the remaining species mostly porous plates occur. The inflorescence axes and leaves generally have equal mixtures of the two forms of plates, the only exception being that the leaves in one of the four species have more scalariform than porous plates. The vessels in the roots have scalariform to reticulate thickenings on the walls, while the thickenings on these elements of the shoot system are often spiral only, and may even be annular. The clearest examples of loosely spiral to annular vessel elements were seen in this family, especially in the stems of *Tradescantia* and *Rhoeo* (fig. 7, 8, 9, and 10).

Cyperaceae: eleven genera, thirty-one species, including *Carex*, *Cyperus*, *Dulichium*, *Eleocharis*, *Eriophorum*, *Scirpus*, *Scleria*, *Stenophyllus*, etc. (representatives of all tribes in Gray's Manual, 1908). The roots in twenty-one species of this family have porous plates with rare scalariform plates in the early-matured metaxylem. In six species there is a more common occurrence of scalariform plates. In the rhizomes, these numbers are respectively 7 and 11, with one species having porous plates only and one having scalariform plates only. In the aerial stems, the numbers are respectively 5 and 23, with one species having scalariform plates only. The numbers in the inflorescence axes are 1 and 9, with one species having porous plates only. Similarly, the numbers in the leaves are 1 and 21, with one species having scalariform plates only. These numbers indicate that the porous plate is most common in the roots and becomes less common as the remainder of the plant is considered in succes-

number of species and the organs in which the various types of perforation plates occur.

sion up to the leaves. The contrary is true of scalariform plates. This general conclusion is true even when the more aquatic types are considered alone, just as it is when the more terrestrial members of this family are treated alone. In other words, the variation that may occur in the same organ in any representative group of species obtains, whether the group is generally more aquatic or generally more terrestrial. No annular or spiral vessels were observed in this family, although further work will be necessary to determine whether any of the elements of this type are actually vessels. Undoubtedly many of them are tracheids, for elements with long tapering ends (fig. 5) and all membranes intact were often successfully separated from the remainder of the xylem.

Dioscoreaceae: *Dioscorea*, with three species. It is perhaps unjustifiable to place this family among those which have vessels throughout the plant, for only aerial stems were available for study. These have very broad vessels with long scalariform plates which often exhibit branching of the bars in the plate.

Eriocaulaceae: *Eriocaulon articulatum* (Huds.) Morong. Vessels with scalariform plates occur throughout the plant in this species, the plates being shorter and less oblique in the roots and rhizomes than they are elsewhere. Furthermore, only the larger elements of the metaxylem in the stems and leaves are clearly vessels. The remainder are tracheids.

Gramineae: thirty-three genera, forty-five species, including the common cereals, members of all tribes as defined by Hitchcock (1935) for grasses in the United States, and a few sub-tropical species. As in the Cyperaceae, the data in table 3 do not adequately demonstrate the true distribution of the perforation plates in the organs of this family. The roots in twenty species have only porous plates. Porous plates with rare scalariform plates in the early-matured metaxylem occur in seventeen species, while in only three species are scalariform plates in any sizeable number present together with the more numerous porous forms. In the rhizomes these numbers are respectively 8, 6 and 1, while in the aerial stems the numbers are 15, 27 and 3. Similarly, it should be stated that in the inflorescence axes, nine species have porous plates only, fourteen have porous plates with rare scalariform plates, and four have a considerable number of scalariform plates together with the porous type. In the leaf, the numbers are respectively 11, 22 and 10. It will be noted that the roots lead in the total number of porous plates and that the leaves are last in this respect. The situation is similar to that in the Cyperaceae, the only difference being that porous plates appear in greater numbers in the Gramineae. The same general distribution seems to occur in all parts of the family, whether the species are from aquatic, mesophytic, or xerophytic habitats. The ratio of porous plates to scalariform plates is the same in corn as it is in wild rice and the same in various bamboos as it is in *Bou-*

teloua gracilis (H. B. K.) Lag. In *Zea*, *Triticum*, and *Avena*, as in practically all other grasses studied, the elements directly above the protoxylem and between the two large pitted vessels of the metaxylem are vessels and not tracheids, as reported by Hayward (1938). This situation is true in both stems and leaves. Favorably macerated materials show that these elements often have perforation plates on oblique end walls where they are likely to be overlooked, even in thin sections. Spiral vessels, chiefly with porous plates, were identified in at least one organ of the shoot system in twenty-two species. They could not be identified with certainty in the roots. Such vessels may occur throughout the family but have been unidentifiable (1) because it is difficult to separate them out in macerations, and (2) because the materials were often not available in a stage of maturation in which these elements were not stretched completely out of their normal shape.

Haemodoraceae: *Lachnanthes tinctoria* (Walt.) Ell. and *Xiphidium coeruleum* Aubl. Porous plates occur in the later-matured metaxylem and scalariform plates in the early-matured metaxylem of the roots in these two species. Scalariform plates alone occur throughout the remainder of the plant, although the long end walls of the larger metaxylem elements in the stem of *Xiphidium* and in the leaf of *Lachnanthes* are not clearly defined perforation plates. No material of the leaf of *Xiphidium* was available.

Juncaceae: *Juncus* with eight species, and *Luzula* with two species. The data in this family, as in the Cyperaceae and Gramineae, may also deserve more detailed treatment than is afforded in table 3. Porous plates do not occur alone in the roots of these species. Porous plates with a few scalariform plates in the early-matured metaxylem occur in four species, and somewhat more equal numbers of porous and scalariform plates in three species. In one (*Juncus militaris* Bigel.), the scalariform type is more numerous than the porous and even occurs in the last-matured metaxylem. In rhizomes, these numbers are respectively one, five, one and one. Similarly, these numbers in the aerial stem are 0, 2, 4, and 4; in the inflorescence axes, 0, 1, 7, and 1; and in the leaves, 0, 1, 2, 3, with one species having scalariform plates alone. A study of these figures indicates that the porous perforation plate is most common in the roots and rhizomes, and least common in the leaves. The aerial stems and inflorescence axes are intermediate in this regard. The variation that occurs in the distribution of perforation plates obtains in general not only when the more aquatic members are considered as a group, but also when the more terrestrial forms are so treated, although there is a tendency for the porous form to occur in greater numbers in the more terrestrial species.

Palmae: twenty-two genera, twenty-six species, including *Adonidia*, *Archontophoenix*, *Caryota*, *Cocos*, *Elaeis*, *Kentia*, *Phoenix*, *Roystonea*, etc. Table 3 gives a clear enough picture of the variation among different organs, although investigations of

a more detailed nature (number of bars in the scalariform plates, for example) would reveal more differences. Twenty-one species in which the roots were examined have both scalariform and porous plates in these organs, although the scalariform plates almost invariably are restricted to the early-matured metaxylem. The stems in eight species have both porous and scalariform plates, while those in fifteen species have the scalariform type (fig. 6) alone. Scalariform plates alone occur in the inflorescence axes of the six species studied, as well as in the leaves of the twenty-two species examined. The perforation plates are also exclusively scalariform in the rachis of the leaf in the species studied. In the stems of a number of species, spiral elements with closely set thickenings were identified as vessels with scalariform plates. No such elements with porous plates were found, and no annular elements were identified as vessels.

Pandanaceae: *Freycinetia Banksii*, *Pandanus Veitchii* Dall., and *P. utilis* Bory. The parts available for study indicate that vessels with scalariform plates are found throughout the plant. Small, scalariformly pitted elements in the roots, stems, and leaves are tracheids.

Smilacaceae: *Rhipogonum*, *Smilax* (five species), *Heterosmilax*, eight species in all. Long scalariform plates occur in the metaxylem in all parts of the plant investigated, except in the rhizome of *Smilax herbacea* L., where only tracheids occur. The vessels tend to be quite broad (175 μ in *S. panamensis* Morong.), especially in the stems. The smaller elements of the metaxylem in this family are tracheids with scalariform pitting in the end walls.

Typhaceae: *Typha angustifolia* L. and *T. latifolia* L. Scalariform plates are found throughout the plant in these species. The plates are clearly defined in the roots, and less so in the shoot system where they are longer. Only the larger elements in the metaxylem of the latter are vessels, the remainder being tracheids. Ink injections confirm these statements.

Xyridaceae: *Xyris flexuosa* Muhl. and *X. Smalliana* Nash. Vessels with porous perforation plates occur in this family in all organs. The wall thickening varies from spiral to reticulate, even in the same vessel member, although the reticulate type is most commonly present. Vessels in the stems and rhizomes are likely to be more heavily thickened, often to the point where elongate pits are left on certain side walls at least.

CONCLUSIONS.—The conclusions in a paper of this nature may be expressed very briefly. Without doubt vessels are lacking in the shoot system of many species in the Monocotyledoneae. In some species vessels are absent throughout the plant. Where present, vessels may have either (1) scalariform (with variations to reticulate) perforation plates with varying numbers of cross bars or (2) simple plates. These observations may be summarized as follows:

1. Many aquatics are without vessels and are often devoid of normal xylem with its familiar tracheary elements.

2. Vessels occur in the roots of all species examined, with the exceptions noted above.

3. In many species, only the roots possess vessels.

4. A small number (twelve) of species have vessels in both the roots and the stems but not in the leaves.

5. The species mentioned in points three and four above may occur in families, as far as they have been investigated, in which other species have vessels throughout.

6. In the species of only two genera were vessels observed in the roots and leaves and not in the stems.

7. Many species have vessels throughout the plant, as in the Gramineae and Cyperaceae.

8. Vessels do not occur in the shoot system of typically bulbous or cormose plants, but are present in the roots.

9. A study of species (a) which have vessels in the root and stem and (b) which have vessels throughout the plant reveals, as earlier pointed out indirectly by the author (Cheadle, 1940), that simple perforation plates occur most commonly in the roots, least commonly in the leaves, and that they are intermediate in their occurrence in the aerial stems.

10. In those species whose leaves have vessels, the ratio of the scalariform plates to simple plates in the leaves is almost invariably greater than that in the stems and still greater than that in the roots.

11. The general distribution of the perforation plates described in the two preceding sentences occurs in species collected from practically all types of environment.

12. Both spiral and annular vessels (with either scalariform or simple plates) were identified in a number of species, especially in aerial stems, where vessels were likewise present in the metaxylem. In anticipation of papers to follow, it appears almost certain that, where both protoxylem and metaxylem are present and vessels are absent from the metaxylem, they are likewise absent from the protoxylem.

It may be stated again that the significance of (1) the presence or absence of vessels and of (2) the distribution of the various types of perforation plates will be discussed in subsequent work.

SUMMARY

A statement is made concerning the scope of the work of which this paper is a part.

The method of macerating tissues as modified for use in treating parts of the plant in the Monocots is described.

The number of genera and species examined, the presence or absence of vessels, and the types of perforation plates are indicated for all organs available in each of the forty-one families discussed.

Many aquatics are without vessels. Vessels occur in the roots of all species examined, with the exceptions noted above, and in many species vessels occur nowhere else in the plant. Typically bulbous and cormose plants have no vessels in the shoot system.

Vessels occur in the roots and stems in some species, but not in the leaves. The genera *Dracaena* and *Cordyline* have species in which vessels occur in the roots and leaves, but not in the stems. In some species vessels occur in all organs. Some families have members with vessels in the roots alone, other members with vessels in the root and stem, and still other members with vessels throughout the plant.

In species which have vessels in the root and stem or which have vessels in the root, stem, and leaf, simple perforation plates occur most commonly in the roots, least commonly in the leaves and are intermediate in their occurrence in the aerial stems. In those species whose leaves have vessels, the ratio of

the number of scalariform plates to the number of simple plates in the leaves is almost invariably greater than that in the stems and still greater than that in the roots. The general distribution of the perforation plates just described occurs in species collected from practically all types of environment.

Both spiral and annular vessels (with either scalariform or simple plates) were identified in a number of species, but only in those which also have vessels in the metaxylem.

CYTOGENETICS OF A FACTOR FOR MULTIPLOID SPOROCTES IN BARLEY¹

Luther Smith

A CONSIDERABLE number of genetic factors have been found in various organisms which disturb the process of meiosis and thus contribute to the analysis of its mechanism and complexities. Descriptions of the irregularities wrought by a number of these factors and reviews of and citations to literature dealing with many others may be found in Darlington (1937), Smith (1936, 1939), and Clark (1940).

The present paper deals with the cytology and genetics of a recessive factor in barley (*Hordeum vulgare*, $n=7$) which affects meiosis in such a manner as to result in meiotic metaphases with 14, 21, 28, 56, 112, or various other numbers of pairs of chromosomes instead of the normal seven. This is apparently accomplished by the assembling of chromosomes from different cells rather than by the repeated division of chromosomes within individual cells.

MATERIALS AND METHODS.—Seed of the “multiploid sporocytes” (symbol *mu*) line was supplied in 1939 by G. A. Wiebe of the Bureau of Plant Industry from a selection out of C. I.² No. 3845, a six-rowed variety. (The mutant was formerly referred to as “contabescent anther.”)

Cytological observations were made on aceto-carmine smear preparations. Whole heads were fixed in Carnoy's fluid for a day or more; root tips for a week or longer. Some smears were made permanent by a tertiary butyl alcohol method described by Sears (1941). Most of the photomicrographs are from slides made permanent by this method.

CYTOLOGICAL OBSERVATIONS.—Typically at diakinesis the pollen mother cells (hereafter referred to as PMC's) have seven pairs of chromosomes as in normal barley though frequently the boundaries of individual cells are not clear. That is, the PMC's in an anther sac tend to form plasmodium-like masses of various sizes in which the chromosomes lie in groups (fig. 1). The numbers in the groups are not large and usually the seven bivalents belonging with a particular nucleolus can be identified.

At first meiotic metaphase the chromosomes form a plate in the PMC material. In some instances this material consists of only one PMC and in others consists of the aggregated cytoplasm of several microsporocytes. In some groups there are 7 pairs, in others 14, 21, 28, 35, 42, etc. As many as approxi-

mately 112 pairs have been counted in a single plate. Such a group is shown in figure 3 and may be compared with the normal as shown in figure 2. Larger groups have been observed, but the difficulty of counting such numbers is obvious. Some typical groups are shown in figures 4 and 5. It is apparent from figure 4 that the chromosomes may line up perpendicularly or horizontally in the tube of PMC material in the anther sac. It is also clear that more than one plate may form within a single mass of PMC material.

There is probably no particular limit to the number of pairs that might gather into a single group or plate. Chromosomes seem relatively free to move within the pollen mother cell material of an anther sac. Thus theoretically if all the PMC's formed into one mass all the bivalents within a locule could line up in a single metaphase plate. This is probably unlikely, but even if it occurred, such a mass would be broken up in making a smear preparation.

Quadrivalents are observed in some polyploid groups (fig. 6). These multivalents occur only in cells with 28 or more chromosomes. This indicates that some cells are sufficiently merged at the time of synapsis to permit pairing between chromosomes that would normally have been in separate cells. In figure 6 two open rings and one zigzag group of four are present. If a translocation were present, there should be about 17 quadrivalents, as there are approximately 238 chromosomes in this group (equivalent of 17 cells). Figure 3, which is from the same plant as figure 6, shows only bivalents; thus a reciprocal translocation is not present.

In addition to the mingling of chromosomes from different “cells” at an early stage, there is evidently a later migration of chromosomes in the formation of some of the polyploid metaphase plates. This is indicated by the concentration of chromosomes in parts of the PMC material, leaving the rest of it lacking in chromatin (fig. 4, 5), and by the greater aggregation of chromosomes at metaphase than at diakinesis. Still further evidence of this movement has been observed in the less complex groups of two cells incompletely fused. In some such instances the chromosomes from one cell have apparently crossed a connecting bridge and joined those in another (fig. 7). In other instances the chromosomes from the two cells have met at their mutual boundary. The connecting bridge between some cells appears so narrow that all the bivalents could not have traversed it simultaneously. The spindle of the merged plate may have a “pole” near the center of each of the two cells (fig. 7, lower right-hand corner), or it may be oriented at various angles to an imaginary line between the centers of the cells.

The movement of the chromosomes in forming the large groups is apparently through considerably greater distances for some of the bivalents than is

¹ Received for publication February 9, 1942.

Cooperative investigations between the Division of Cereal Crops and Diseases, Bureau of Plant Industry, U. S. Department of Agriculture, and the Field Crops Department, Missouri Agricultural Experiment Station. Journal Series No. 776.

The writer wishes to express his appreciation to G. A. Wiebe for the seed which resulted in this study. Thanks are also extended to Harland Stevens and John L. Toevs of the Aberdeen Substation of the Idaho Experiment Station for their kindness in providing field and laboratory facilities in the summer of 1940.

² C. I. refers to accession number of the Division of Cereal Crops and Diseases.

ever accomplished in the formation of a plate in normal organisms.

One question which arose was whether the groups were always composed of seven or multiples of seven pairs, that is, whether the seven bivalents associated with a given nucleolus acted as a unit. Usually the larger groups are multiples of seven. Only a few have been observed which had other than seven or a multiple of seven pairs of chromosomes. One of these had 9, another 4 (fig. 8) and a third 16 or 17.

The foregoing is a description of the typical behavior, but there is some variability. Normal meiosis has been observed in anthers from the central florets of a spike, while large groups of chromosomes were found in anthers from lateral florets of the same spike. Even if the central florets exhibit the peculiar behavior, the groups of chromosomes tend to have 14 or 21 pairs rather than larger numbers. Meiosis in the central florets is less abnormal in plants grown in the greenhouse than in those grown in the field. Normal microsporogenesis has not been observed in the lateral florets. Thus the fusion (or incomplete separation) of PMC's varies from the occasional incomplete merging of two cells to the other extreme where there is only infrequently a cell which is not merged with several to many other cells.

First anaphase (and later stages) proceeds at about the same tempo in the groups with many chromosomes as in those with only 7 pairs (fig. 4). At late anaphase in the larger groups the chromosomes do not converge on a point. From the shape and size of the spindle in these groups it is doubtful if there is any point which functions as a "pole" in the usual cytological sense of the term. In this respect the spindle is similar to the divergent meiotic spindle in maize described by Clark (1940).

In many groups the spindle is obviously much shorter in proportion to its width than normal, i.e., the spindle is much wider, but little if any longer. It seems to extend only a short distance beyond the centromeres of the chromosomes regardless of how much PMC material may lie beyond or how many chromosomes are in the group. In anaphase the chromosomes move apart about the same distance as in normal plants, though the movement is frequently not limited by the bounds of the PMC material. Evidently the movement is stopped by some other mechanism, such as possibly the inability of a repelling force (electromagnetic, or protoplasmic streaming?) to push them further apart. The movement may be

limited by the termination of the spindle but, as pointed out above, in many instances there is no apparent obstruction to the further extension of the spindle.

At first telophase there is apparently a tendency for the chromosomes to form a spherical nucleus as in normal plants, but, if the number of chromosomes is large, an elongate nucleus is formed (fig. 9).

The second division usually proceeds with no more irregularities than might be expected from the number of chromosomes in the groups. In a few instances three second telophase nuclei were formed instead of four, indicating that cytokinesis following the first division was imperfect in these instances at least.

The microspores vary in size from much larger to smaller than normal. (Immature microspores of a normal plant and an *mu* plant are shown in fig. 10 and 11.) They are frequently irregular in shape, and two or more may appear to have united or to have been only partially separated by cytokinesis following the second meiotic division (fig. 11). In such fused spores with the contents continuous, the nuclei may be separate or united. Probably in the division of the cytoplasm of the large PMC masses, some portions contained no chromosomes. Some of these presumably remained attached to nucleated material. In the larger spores two or more nucleoli of various sizes are common, though one nucleolus is characteristic of normal barley microspores. The number and size of the nucleoli would, of course, depend on the number of nucleolar organizing, satellited chromosomes present and on how many nucleoli had fused.

The mature spores are wholly, or almost wholly, without starch (fig. 12, 13). It is apparent from these photomicrographs that the lateral florets (fig. 13) are more irregular than the central florets (fig. 12) at this stage as well as at meiosis.

A number of minor irregularities are observed in *mu* plants. (1) There is frequently a greater mixture or range of stages on a slide than is found in slides from normal plants. (2) At first metaphase in some cells the chromosomes are not condensed and shortened to the same degree as in normal plants. Therefore, the chromosomes appear long and tenuous. This condition appears in cells with only 7 pairs as well as in those with many (fig. 14). (3) Some chromosomes undergo equational division at first anaphase (fig. 15). (4) Univalents are occasionally present, and these may account for the equational divisions

Fig. 1-9.—Fig. 1. Diakinesis in a multiploid sporocytes (*mu*) plant of barley. No clear boundaries are present between the cells, and some groups of chromosomes (and nucleoli) are in proximity. $\times 390$.—Fig. 2. First meiotic metaphase in a normal plant of barley. There are seven bivalents. $\times 850$.—Fig. 3. A first meiotic metaphase group in an *mu* plant containing approximately 112 pairs of chromosomes. Groups with larger numbers have been observed. $\times 390$.—Fig. 4 and 5. Ribbons of pollen mother cell material in which groups of chromosomes are at first meiotic metaphase or anaphase. In figure 4 the groups are arranged along or across the ribbon of PMC material. It is also apparent in this figure that there is no striking difference between the timing of stages in the large and small groups. In both figures 4 and 5 it is clear that the spindle must be shorter in relation to the width than normal. Figure 4, $\times 390$; figure 5, $\times 190$.—Fig. 6. First meiotic metaphase in the same plant as figure 3. There are about 113 bivalents plus 3 quadrivalents (one near each end opened out into a ring, one zigzag at extreme right). $\times 680$.—Fig. 7. First metaphases in an *mu* plant showing how the chromosomes migrate (arrows) from one PMC to another or assemble along a common boundary between two cells. $\times 390$.—Fig. 8. First metaphase in an *mu* plant showing a group of 4 bivalents. $\times 850$.—Fig. 9. First meiotic telophase. The nuclei are elongate and near one end of the PMC material. $\times 390$.

mentioned in statement (3), or some chromosomes may undergo both equational and reductional divisions at the "first" division. Such "false univalents" were described by Darlington (1929) in hyacinths. (5) At first anaphase and later stages, few to many fragments are observed in some groups. These fragments and the tenuous chromosomes are not common in normal plants of barley but have been reported in a number of organisms and are probably due to unexplained physiological upsets.

Mitotic divisions in root tips and tapetal cells of *mu* plants appear normal (fig. 16) and all those counted had 14 chromosomes. Four of these fourteen chromosomes have satellites as in normal plants. The fact that *mu* individuals develop at about the same rate and attain almost the size of normal plants is further indication that mitosis is normal.

DESCRIPTION OF AFFECTED PLANTS.—At Aberdeen, Idaho, 1940, the progeny of a plant heterozygous for the "multiploid sporocytes" factor was measured for height. The average of 145 normal plants was 33.4 inches. The average for 37 *mu* plants was 31.1 inches. Affected plants were therefore somewhat reduced in height. Affected plants in this population, as in others, did not differ much in rate of growth or date of maturity. However, when the normal plants were near the hard dough stage, and were still green, the spikes of *mu* plants had turned a rich, golden yellow, so that affected plants could be distinguished by the color of the heads as well as by the absence of seeds. The yellow color of spikes on *mu* plants was brighter than the color of ripe spikes of normal plants and resembled the latter only superficially. The leaves at this stage were similar in color to those of normal plants. In another population 41 *mu* plants averaged 15 tillers while 16 *mu* sibs averaged 14 tillers per plant.

Anthers of *mu* plants apparently cease development shortly after meiosis. At flowering they are smaller and thinner than normal (fig. 17) and have a sickly, yellowish color.

"Multiploid sporocytes" plants rarely produce seed even when pollinated with pollen from normal plants. Though meiosis in anthers in some central florets seems to produce microspores with the normal complement of chromosomes, these anthers abort as do those in other florets of the head, and the spores are almost entirely lacking in starch. Megasporogenesis has not been studied though it is probably abnormal also since no seeds have been obtained by pollinating *mu* plants with pollen from normal individuals. This is not conclusive evidence, of course,

since other causes could prevent the development of seeds.

A few seeds have been found on affected individuals. Sixteen plants from such seeds found and grown by Harland Stevens at Aberdeen, Idaho, were examined by the writer. Of the 16, 7 were normal and 9 were *mu*. If the seeds had arisen from self-fertilization, all the plants would have been *mu mu*, whereas only 9 of the 16 were. This would indicate that the seeds probably arose from chance pollinations by nearby heterozygous sibs. Of the 7 plants which were not *mu mu* 4 were tested and found to be *Mu mu*. All 16 plants had 14 chromosomes. Even if the megaspore mother cells had produced ovules with 14 or more chromosomes, triploids, etc., might be rare or not occur, since it is a common observation that autotetraploids and parental diploids cross with difficulty if at all. The situations are not quite comparable, since the somatic tissues are all diploid (2n) in the case of the diploid plant with diploid (or polyploid) megaspores pollinated by pollen from a normal plant, and there are 4n and 2n somatic tissues in the respective individuals concerned in the tetraploid by diploid cross. However, the writer has studied a meiotic irregularity in einkorn wheat (*Triticum monococcum*) which results in a high proportion of diploid spores (microspores and apparently megaspores as well) and has observed no triploids but only diploids and unstable tetraploids among several hundred progeny. Certainly it appears that in this *T. monococcum* mutant there is selection against combinations of gametes which would result in triploids.

DISCUSSION.—The present paper adds another to the increasing number of observations on irregularities in the meiotic process and furthers the accumulation of evidence showing that meiosis is a delicately balanced series of changes which may be modified in devious ways at various stages. The mutant herein described furnishes an opportunity to observe meiosis under conditions of incomplete separation or fusion of pollen mother cells. Under these circumstances the bivalents at first meiotic metaphase are not widely dispersed in the microsporocyte material, but on the contrary, bivalents from many "cells" tend to congregate into a single metaphase plate. Such aggregation suggests more the effects of protoplasmic streaming than the effects of electromagnetic forces, since at metaphase the bivalents would presumably not be drawn together from considerable distances by magnetic

attraction but would rather be kept apart, according to the conception of some cytologists.

This mutant also demonstrates that the spindle may be greatly increased in width without materially affecting its length, just as in certain other mutants and some hybrids the spindle has been observed to be much longer but little if any wider than normal. It was further apparent that the length of the spindle was largely independent of the size and shape of the pollen mother cell mass.

SUMMARY

A recessive factor in barley ($n=7$) was discovered which interferes with the normal development and behavior of a few to most of the microspores. As a result the number of bivalents in different metaphase plates varies from fewer than 7 to more than 100. In some groups quadrivalents are present, indicating that the chromosomes from dif-

ferent cells were in proximity at an early stage and were able to synapse, presumably because there was no barrier between them. It is also possible that cytokinesis was suppressed in some premeiotic divisions. In other groups, there is evidence that migration of the chromosomes took place in the formation of the metaphase plates. In large groups the spindle is many times wider than normal, but the length is not greatly changed. The microspores are variable in size and practically devoid of starch. Fertility is very low even when the florets were artificially pollinated with normal pollen. Mitosis is apparently regular, and affected plants are only slightly smaller than normal.

EFFECTS OF MERCURY VAPOR UPON SEED GERMINATION ¹

Netta E. Gray and Harry J. Fuller

THE TOXIC effects of mercury, mercury compounds and mercury vapors upon animal organisms have long been known by animal physiologists, but relatively few investigators have studied the effects of these substances upon plants. The most searching experiments upon this subject have been those of Zimmerman and Crocker (1934), who studied the effects of mercury and of fourteen organic and inorganic mercury compounds upon the growth and development of actively growing angiospermous plants belonging to seventy-five genera. The plants were subjected to the mercury and mercury compounds in various ways: plants were enclosed within glass cases or placed under bell jars together with small receptacles containing metallic mercury or crystals of mercury compounds; plants were enclosed in similar cases within which were placed receptacles containing soil, sand, or tankage, to which metallic mercury or various mercury compounds had been added; plants growing under commercial greenhouse conditions were subjected to mercury vapors escaping from a single bench of rich soil containing mercuric chloride. These investigations indicated that growing plant parts, particularly flowers and leaves, are injured by exposure to mercury and mercury compounds. Plants of sixty-five genera proved to be dis-

tinctly susceptible to such injury, which was more pronounced in peach seedlings at higher temperatures (50°F. and above) than at lower temperatures (40°F. and 35°F.). The injury induced by the vapors from metallic mercury was very similar to that caused by vapors emanating from soils treated with mercuric chloride. This fact, coupled with the fact that vapor of metallic mercury was detected in the air above soil samples treated with the mercury compounds, is assumed to indicate reduction to the metallic state in the soil. Zimmerman and Crocker have reviewed briefly the few earlier papers on the subject, all of which treat of the effects of mercury or mercury compounds upon actively growing plant parts. Insofar as the authors of this paper have been able to determine, there have been no reports upon the effects of mercury vapor upon dormant seeds and young seedlings.

METHODS.—The experiments reported in this paper were arranged as follows:

Series I: Dry seeds of pea (Alaska), corn (Reid's yellow dent), bean (Burpee's Stringless Green Pod), radish (Scarlet Globe), sunflower, and cucumber (Early White Spine) were placed in open glass containers under a bell jar of approximately 15-liter volume, under which there was also included a 100 cc. beaker containing 50 cc. of metallic mercury. The

Beans	13 da.	32.3 cm.	30.6 cm.	13 da.	26.9 cm.	25.4 cm.
Radish	32 da.	8.2 cm.	8.5 cm.

bell jar was sealed to a ground-glass plate by means of petroleum jelly. The bell jar with the enclosed seeds and mercury was placed in a constant-temperature (21°C.) darkroom on April 1, 1940, and was allowed to remain there until October 1, 1940. At the end of this six-month period, 200 seeds of each species were placed in germinating pans and in moist sawdust in flats and in pots, and the percentage and rate of germination were determined; in addition, in some instances, measurements of seedling length and seedling dry weight were made to determine whether post-germination effects of the exposure to mercury were apparent. A control set of 200 seeds of each species was kept in another darkroom under similar conditions, but was not exposed to mercury vapor.

Series II: Seeds of pea, bean, radish, and corn were placed upon moist filter paper in Petri dishes, which were kept under bell jars, as described above for series I, together with a 100 cc. beaker containing 50 cc. of mercury. Determinations of the percentage and rate of germination of 100 seeds of each species were made at intervals, which varied for the different species used. Controls consisted of seeds germinated under similar conditions, except that they were not exposed to the mercury vapor.

Series III: Seeds of pea, bean, and corn were planted in moist sawdust in four-inch pots, which were placed in glass cases, approximately 4 feet x 3 feet x 3 feet. The cases were kept in a greenhouse,

the daily temperature of which fluctuated from 17° to 22°C. In each of three such cases, a Petri dish containing 15 cc. of mercury was placed beside the pots. In two of these cases one drop (.1 cc.) of mercury was thoroughly mixed with the sawdust before the pots were filled, in addition to the open dishes of mercury placed in the cases; in the third case, no mercury was added to the sawdust. Three similar cases were set up as controls. In two of these cases the sawdust was prepared with mercury as above and the third was left entirely without mercury.

RESULTS.—The results of these three series of experiments are presented in the following tables. In tables 1 and 2 are presented data from experiments of series I; in these tables only germination percentages and seedling lengths are recorded.

The data presented in tables 1 and 2 show clearly that there are no significant differences between control seeds and seeds subjected for six months to mercury vapor in the percentages of germination and in the early stages of seedling growth.

In table 3 are presented data from experiments in series I, showing the effects of mercury vapor upon the percentage of seed germination, seedling length, and seedling dry weight in six species, seeds of which were stored in the presence of mercury vapor for six months. In this experiment, the seeds were germinated in sawdust in flats, which were kept in a greenhouse room. Each of the figures in the

and seeds exposed for six months to mercury vapor, with reference to percentage of germination, seedling length, and seedling dry weight, when the seeds were germinated and grown under greenhouse conditions.

In table 4 are presented data from series II, showing the percentage and rate of germination of seeds germinated in the presence of mercury vapor.

These data show that the mercury vapor present did not influence appreciably the percentage of seed germination, but that it did decrease somewhat the rate of germination in beans, corn, sunflower, and cucumber.

Graph 3. Bean seedlings grown in mercury vapor. A and B: Drop of mercury mixed with sawdust in each case. C: Dish of mercury set in the case. D and E: Drop of mercury mixed with sawdust and also an open dish of mercury in each case.

The results of series III are presented in graphs 1, 2, and 3, which show the growth in stem length in the various experimental cases. In these graphs, each curve represents the average of measurements on twenty seedlings. As the graphs show, the best growth of seedlings of peas, corn, and beans occurred in the controls, which contained no mercury. The growth of the seedlings grown without mercury in the substratum but with mercury in the Petri dishes in the glass cases was poorer than that of the controls. Poorest growth occurred in the seedlings grown in the cases in which mercury was present in the substratum as well as in the Petri dishes in the cases.

SUMMARY

Seeds of pea, corn, bean, radish, sunflower, and cucumber, stored for six months in nearly air-tight containers in the presence of mercury vapor suffered no ill effects as a result of that storage, for they showed no decrease in percentage of germination or in early seedling growth, as compared with seeds not exposed to mercury.

There was slightly delayed germination of seeds of these species when germinated in the presence of mercury vapor as compared with the germination of

seeds not germinated in mercury vapor. The final percentage of germination of the seeds grown in the presence of mercury vapor was not appreciably different, however, from the germination percentage of seeds not germinated in mercury vapor.

Seedlings of peas, corn, and beans grown in the presence of mercury vapor in the surrounding air and mercury in the substratum grew more poorly than seedlings grown with mercury vapor present only in the air. Seedlings under both these conditions grew more slowly than seedlings completely removed from mercury and, in addition to their stunted growth, showed other signs of injury: yellowing of leaves, failure of leaf development, and early leaf fall.

THE EFFECT OF VITAMINS ON TEN STRAINS OF SACCHAROMYCES CEREVISIAE¹

Leon H. Leonian and Virgil Greene Lilly

Bios is a collective term; it includes a number of growth substances required by different strains of yeasts. Five of its members are now available as chemically pure compounds; they are thiamin, pyridoxin, inositol, pantothenic acid, and biotin. Additional factors, known to exist in liver, in yeast extract, and in other organic substances, are yet to be isolated in pure form. While these may induce significant increases, they do not constitute critical factors in growth; therefore, it is now possible to conduct fundamental studies in the nutrition of yeasts without resorting to various "concentrates" which, in the absence of the pure substance served as growth factors. The work of Williams, Eakin and Snell (1940) is the only important one on the interaction of the foregoing five substances. For a comprehensive survey of the more pertinent literature on this subject the reader is referred to Williams (1941).

In the following experiments, the writers used ten strains of *Saccharomyces cerevisiae* and all possible combinations of the five growth factors.

MATERIALS AND METHODS.—The following is a list of cultures of *Saccharomyces cerevisiae* used in this work:

1. "Old Process," secured from American Type Culture collection.

¹ Received for publication February 26, 1942.

Published with the approval of the director of the West Virginia Agricultural Experiment Station as Scientific Paper No. 279.

2. "Gebrüder Mayer," secured from American Type Culture collection.
3. "Fleischmann," isolated from a cake of yeast.
4. "Red Star," isolated from a cake of yeast.
5. ATCC2331, received from National Regional Research Lab., Peoria, Ill.
6. "Botton Yeast," originally from Kluyver, Delft, Holland. Obtained from the Department of Agricultural Bacteriology, University of Wisconsin.
7. "Top Yeast," same origin as No. 6.
8. National Grain Yeast Corporation yeast No. 1, received from Regional Laboratory, Peoria, Ill.
9. National Grain Yeast Corporation, yeast No. 2, same origin as No. 8.
10. Originally from Pasteur Institute, Paris; this has been used extensively in growth factor studies; obtained from the Regional Laboratory, Peoria.

The following nutrient solution was used as standard medium:

Dextrose	25	gm.
l-aspartic acid	1.50	gm.
(NH) ₄ SO ₄	0.75	gm.
KH ₂ PO ₄	1.0	gm.
MgSO ₄ ·7H ₂ O	0.50	gm.
Na ₂ CO ₃	0.60	gm.
Tl ₂ SO ₄	0.8	mg.
ZnSO ₄ ·7H ₂ O	1.0	mg.
MnSO ₄ ·4H ₂ O	1.77	mg.
H ₃ BO ₃	1.0	mg.
Fe(NO ₃) ₃ ·9H ₂ O	1.5	mg.
CuSO ₄ ·5H ₂ O	0.1	mg.

KI	0.1 mg.
Thiamin chloride ²	1 part in 20 million
Pyridoxin hydrochloride	1 part in 20 million
Calcium pantothenate	1 part in 20 million
i-inositol	5 parts per million
Biotin methyl ester	1 part in 2 billion
Distilled water	1,000 ml.

This solution was adjusted to pH 5.0 before sterilization. When used for stock cultures, 0.02 per cent yeast extract (Difco) was added to insure a more vigorous growth. The vigor of the stock cultures and that of the inoculum, which is removed from such cultures and transferred to the test solution, has an important bearing on the final results. If a given inoculum is not taken from a culture of optimum vigor, its behavior often becomes erratic and the results unreliable. All stock cultures for inoculum were carried on a liquid medium with 25 ml. of the nutrient solution per 250 ml. flask. After incubating at 25°C. for three days the cultures were ready to furnish inoculum. This consisted of one standardized loopful of the cell suspension for each flask to be inoculated. The platinum wire was B & S 24-gauge, double loop, with an inside diameter of 2.5 mm. Such a loop removes approximately 0.01 mg. of cells (calculated on the dry basis) from the stock solution. The culture flasks were arranged on a motor-driven shaker which was timed to agitate the cultures for ten minutes every hour. After incubating for various lengths of time, the yeast cells of each flask were filtered separately through alundum crucibles RA-360 under a vacuum of 650 mm. Hg. The cells were then washed three times with distilled water, dried at 85°C. and weighed. After that, the crucibles were washed, heated in a muffle furnace at 800°C., cooled, washed with three changes of distilled water, dried at 85°C. and tared. This was repeated after each harvest. When less than 5 mg., the determinations were made with the aid of an electrophotometer.³

Every experiment reported in this paper was repeated at least three times, some as many as ten times. The cultures were always made in duplicate. Thus, each figure in the following tables represents the average of at least six, and often as many as twenty determinations. As a general rule, the results were fairly close and reproducible, but whenever the nutritional deficiencies were too acute, the behavior of the yeasts was more erratic. This necessitated a great number of determinations before a satisfactory average could be established.

Strict bacteriological methods were employed throughout the work, and all glassware was thoroughly cleaned before using. Cotton used for plug-

²Thiamin chloride, pyridoxin hydrochloride, and calcium pantothenate were obtained from Merck, biotin methyl ester from SMACO, and inositol from Pfanstiel.

³The writers have observed considerable discrepancy between electrophotometer readings and actual weights. The same weight of different strains of yeasts may give different readings on the machine. Furthermore, the same weight of a given strain of yeast grown under different conditions, may give readings varying as much as 200 per cent.

ging was first placed in a large Barnstead Soxhlet extractor and extracted with 90 per cent alcohol for twenty-four hours. This eliminated or critically reduced the growth factors present in the cotton.

Some investigators practice a thorough washing of the cells before using them for inoculum. This, so far as our own conditions were concerned, was unnecessary. After three days' growth the yeast did not leave any appreciable amount of growth factors in the medium. This was demonstrated by filtering three-day-old cultures, adding salts, aspartic acid, and dextrose, adjusting the pH, sterilizing, and inoculating with yeasts; no appreciable growth followed. But when the necessary vitamins were added to this medium a good growth resulted. Furthermore, one loopful of the standard solution containing all the vitamins, when added to a flask of medium containing no vitamins, failed to produce any growth; nor did five or ten loopfuls; twenty loopfuls induced very faint growth, about 0.2 mg. per flask.

TIME, TEMPERATURE, QUANTITY-OF-INOCULUM FACTORS.—The filamentous fungi, heterotrophic with respect to vitamins, cannot make any appreciable growth without the presence of an exogenous supply of these substances, regardless of time. Such is not the case with the strains of yeast used in this work. If given enough time, they will make some growth; often this growth is considerable. Therefore, in studies on the nutrition of yeasts, it is imperative to establish a time standard for obtaining an optimum growth. Since yeasts make a more rapid growth at comparatively high temperatures, time and temperature standards must be established simultaneously. There is still a third important factor, namely, the quantity of inoculum. Where a quantity of inoculum weighing no more than 0.01 mg. may induce no growth within a certain period, another inoculum of the same yeast weighing 0.2 mg. may produce a fairly good growth. At best, however, any quantity-of-inoculum factor must be an arbitrary one. The writers have selected 0.01 mg. (estimated on the basis of dry weight) because it was found to be very convenient and can be easily duplicated.

One may establish a particular time-temperature-quantity-of-inoculum standard and find it still inadequate because some yeasts require a comparatively short period to attain their optimum growth when there is no critical nutritional condition, such as exists in the absence of one or more growth factors from the medium; when such a condition exists, a longer period may be required. Consequently, the time factor cannot be uniformly standardized. Williams *et al.* (1940) believe that twenty-four hours at 30°C. is the most interesting and practical length of time, and that longer periods are chiefly of academic interest. The important factor to consider is whether or not a given length of time will enable the growth of a given yeast to attain a dependable equilibrium despite deficiencies in the medium. The writers have found that at 25°C. reproducible results could not be obtained within twenty-four and, in many cases, within forty-eight hours. However,

after seventy-two hours a greater uniformity was observed among the results of different replications of a given experiment. Consequently, seventy-two hours at 25°C. has been established as the most satisfactory time-temperature standard. Nevertheless, the more pertinent results obtained with a shorter period have also been recorded (table 2).

EXPERIMENTS.—Only thirteen combinations of vitamins (out of the possible thirty-one) induced any growth; all others failed. After seventy-two hours' incubation, there was no growth in solutions containing no biotin. Only yeast no. 10 occasionally made a slight growth; oftener it failed to grow. Perhaps it should be stated that by "no growth" we do not wish to convey the idea that the inoculum did not increase to some extent; we merely mean to state that to the eye the medium remained clear. There was no growth when biotin and one or more other growth factors were left out; nor did any growth occur when thiamin, pyridoxin, inositol, pantothenic acid, and biotin were added singly to the medium. Williams *et al.* (1940) report that Gebrüder Mayer, Old Process and Fleischmann yeasts made considerable growth in the presence of pantothenic acid alone, and that the last-mentioned yeast made a good growth in the medium to which only biotin was added. Results obtained under our conditions fail to support this assertion of Williams *et al.* The following combinations also failed to support any growth in any of the yeasts: thiamin and pyridoxin, thiamin and pantothenic acid, thiamin and inositol, thiamin and biotin, pyridoxin and pantothenic acid, pyridoxin and inositol, and pyridoxin and biotin. There was no growth in the control. This is contrary to the results

of Williams *et al.*, who reported discernible growth in their blanks at the end of three days.

Table 1 gives the results obtained after seventy-two hours at 25°C. Each figure indicates the average growth per flask of 25 ml. solution. The yields that are less than 1 milligram per flask should not be regarded as significant; for all practical purposes they may be considered as showing no growth.

Table 1 shows that with the exception of yeasts no. 8 and 9 all others produced uniformly high yields when grown in the standard solution containing all five growth factors. When, however, 0.02 per cent yeast extract was added to this medium, the yield of no. 8 was 71 mg. as compared with 40 in the standard solution, and that of no. 9 was 73.1 instead of 45.5. The yield of all yeasts except that of no. 5 was from 70 to 74 mg.; no. 5 produced 66.3 mg.

When thiamin alone was left out, the Old Process yeast was the only one affected; its yield dropped from 54.1 to 10.7 mg. When pyridoxin was left out, no significant changes in the yield of any yeast was observed; but when both thiamin and pyridoxin were omitted, the yield of Old Process further decreased from 10.7 to 3.2 mg., and yeasts no. 5 and no. 9 sharply reduced their yield to 14.9 and 11.4 mg., respectively. This shows that both thiamin and pyridoxin play an essential role in the growth of these yeasts, and that, while an organism may be able to synthesize thiamin in the presence of pyridoxin or synthesize the latter in the presence of thiamin, it cannot effectively synthesize both vitamins at the same time, at least not within a period of three days.

TABLE 1. The effect of growth factors on yeast as expressed by the weight in mg. of dry cells per flask after incubation of seventy-two hours at 25°C.

Treatment	Yeast 1	Yeast 2	Yeast 3	Yeast 4	Yeast 5	Yeast 6	Yeast 7	Yeast 8	Yeast 9	Yeast 10
All five factors present	54.1	62.0	50.0	56.3	52.2	58.6	52.9	40.0	45.5	54.9
Minus thiamin	10.7	60.6	50.3	53.3	51.1	58.1	54.6	40.2	45.3	56.7
Minus pyridoxine	57.4	58.8	50.2	55.9	49.3	61.9	52.1	39.8	44.3	54.0
Minus inositol	7.2	13.8	50.2	56.2	55.7	64.6	17.1	43.6	4.8	57.1
Minus pantothenic acid ...	8.7	3.0	0.5	3.5	1.4	20.2	0.6	0.5	0.5	5.0
Minus biotin	0.4	0.3	0.4	0.3	0.4	0.4	0.3	0.3	0.3	0.6
Minus thiamin and pyridoxine	3.2	59.2	50.0	54.0	14.9	55.9	60.1	41.9	11.4	52.5
Minus thiamin and inositol.	0.4	8.6	53.6	40.0	59.1	53.5	16.9	37.1	0.9	55.2
Minus thiamin and pantothenic acid	6.4	2.5	0.5	4.2	15.6	51.3	0.4	0.3	0.4	7.3
Minus pyridoxine and inositol	12.1	19.3	51.4	44.4	51.1	61.6	8.1	41.9	2.5	53.5
Minus pyridoxine and pantothenic acid	4.3	0.5	0.5	0.4	6.8	23.1	0.3	2.5	0.3	5.7
Minus pantothenic acid and inositol	2.4	1.3	0.3	1.6	5.1	25.4	0.3	0.2	0.2	6.7
Minus thiamin, pyridoxine, pantothenic acid	2.5	2.7	0.6	4.4	5.9	52.4	0.3	0.3	0.7	6.4
Minus thiamin, pyridoxine, inositol	2.4	7.7	47.9	43.5	7.2	54.3	13.3	29.8	0.5	53.6
All five factors plus 0.02% yeast extract	71.2	74.8	72.7	74.8	66.3	70.5	73.6	71.0	73.1	71.2
Control: No growth substances added	0.3	0.4	0.4	0.4	0.3	0.3	0.3	0.4	0.4	0.4

Only four yeasts, no. 1, 2, 7 and 9, manifested a sharp reduction in yield when inositol alone was left out of the medium; when inositol and thiamin both were left out, the yield of yeast no. 1, 2 and 9 was further reduced, and that of no. 7 remained the same. Yeast no. 4 which was unaffected when either thiamin or inositol alone was left out, reduced its yield from 56 to 40 mg. when both of them were omitted. In the absence of pyridoxin and inositol, yeast no. 2 did not show any further reduction; in fact, it did slightly better. Yeast no. 7, on the other hand, was reduced from 17.1 mg. when inositol alone was left out, to 8.1 when both inositol and pyridoxin were omitted. Yeast no. 9 also manifested a reduction. However, when yields become very small, the differences may seem very large on the percentage basis, and insignificant on the basis of actual yield produced.

In the absence of pyridoxin and pantothenic acid, or inositol and pantothenic acid, the yield of all ten yeasts was sharply reduced. This was to be expected because the omission of pantothenic acid alone brings about a sharp reduction.

Yeast no. 6 made a better growth in the absence than in the presence of inositol. When only inositol or only biotin was added to the medium, no growth ensued, but in the presence of inositol and biotin together this yeast made almost as good growth as it did in the presence of all five growth factors. Thus, the addition of an apparently unnecessary substance to biotin made the difference between growth and no growth. Similarly, pantothenic acid alone failed to induce any growth in this yeast; added to biotin, it helped to produce an excellent growth. When supplied with biotin, and either pantothenic acid or inositol, yeast 6 synthesized the missing factor. Another significant fact to be noted is that in the presence of all five vitamins this yeast produced 58.6 mg. of cells; when thiamin was omitted, the yield remained the same; when pyridoxin and pantothenic acid were omitted, the yield was reduced to 23.1 mg., but when thiamin, pyridoxin, and pantothenic acid were left out, the yield was 52.4 mg. Apparently thiamin is toxic in the absence of pyridoxin and pantothenic acid.

Yeast 10 attained its optimum growth when pantothenic acid and biotin alone were added to the medium; yeasts 3 and 4 showed a slight decrease, while the yield of no. 8 was reduced from 40 to 29.8 milligrams.

THE EFFECT OF HEAVY INOCULUM.—The amount of inoculum was increased from 0.01 mg. to 0.2 mg., and all the work reported in table 1 was repeated. Three-day-old cultures were allowed to stand for three hours to allow the yeast to settle. The clear solution was then poured off, leaving behind nearly all of the cells and 1 ml. of the solution. One loopful of this heavy suspension, estimated to contain twenty times the amount of cells in the light inoculum, was transferred to each flask. Only a few of the more pertinent results are given here. In the absence of thiamin, the Old Process yeast failed to show any

increase in the yield when the inoculum was twenty times the normal amount. However, in the absence of inositol its yield was doubled by the heavy inoculum; that of Gebrüder Mayer increased from 13 to 35 mg., while yeast no. 9 increased from 4.8 to 28 mg. When pantothenic acid was omitted, the yield of yeast no. 4 went up from 3.5 to as much as 50 mg. However, the growth was not always as much as this, but sometimes varied down to 16 mg. When pantothenic acid was omitted, yeasts 3, 5, 7, 8 and 9 failed to make any appreciable growth either with light or with heavy inoculum. These five yeasts manifested a similar indifference to heavy inoculum when both pantothenic acid and inositol, pyridoxin and pantothenic acid, and thiamin and pantothenic acid were omitted. When all other growth factors were present except biotin, the heavy inoculum did not induce more than 1 to 4 mg. of cells in all cases except yeast no. 10, where the yield varied from 20 to 40 mg.

Why in so many cases did a heavy inoculum induce good growth while a light inoculum failed? The first answer that comes to mind is that the larger numbers of cells carry enough of the missing vitamin into the deficient medium to induce growth. However, this explanation does not rest on a sound basis as shown by the results of the following experiment: One loopful each of a heavy suspension of cells (0.2 mg.) of yeast no. 4 was transferred to a number of flasks containing 25 ml. of the nutrient solution and all the growth factors except pantothenic acid. Some of the flasks were boiled over an open flame for five minutes to kill the yeast cells and to extract their vitamin content; the solution was then cooled and reinoculated. The remaining flasks were not boiled. After an incubation period of seventy-two hours the cells were harvested. The boiled solutions yielded only 3 mg. per flask while the unboiled ones yielded 30 to 45 mg. This shows that the pantothenic acid content of 0.2 mg. yeast cells was too small to have any effect, and that the factor responsible for the increased growth was associated with the living protoplasm. It may be argued that some thermolabile substance present in the cells stimulated the living protoplasm into synthesizing vitamins. However, this does not seem to be the case because various amounts of acetone extracts and chloroform dialyzate, obtained without heat and aseptically, failed to induce increased growth. Some may reason that each living cell of the inoculum, being unable to multiply extensively in a deficient solution, will cease to grow after exhausting its reserve supply of vitamins; consequently, the larger the inoculum, the larger will be the yield. This explanation would deserve consideration if the differences between the results of the light and the heavy inoculum were no more than a few milligrams; but we have seen that often a heavy inoculum in a deficient solution may bring about an increase of several hundred per cent. We know that one loopful of a heavy suspension of yeast cells contains such an infinitesimal amount of pantothenic acid as to be entirely ineffective in a medium lacking this vitamin. Our experiments have shown

that 1 part of pantothenic acid in 250 million parts of the medium induces but 4 or 5 mg. of cells of yeast no. 4; this is not much more than the growth made in the total absence of pantothenic acid. In another experiment the amount of inoculum per flask was increased to 30 mg. This much inoculum was placed in a flask containing 25 ml. of the nutrient solution but with none of the vitamins. Some of the flasks thus prepared were boiled and re-inoculated without filtering off the insoluble parts of cells; others were left unboiled. The latter yielded a total of 52 mg. of cells per flask and the former only 32 mg. After deducting from this 32 mg. the weight of the insoluble parts which resulted from the boiling of 30 mg. of inoculum, there remained only 18 mg. of cells per flask of boiled solution. In other words, 30 mg. of the yeast cells contained enough vitamins to produce 18 mg. of new cells. Thus, a heavy inoculum consisting of 0.2 mg. of cells contains enough vitamins to induce a yield slightly more than 0.1 mg. of new cells per flask, a very insignificant growth. According to these results, therefore, the carrying-over phenomenon may be considered as being of no consequence whatever.

The writers offer the phenomenon of dissociation, and probably that of segregation, in explanation of the effect of heavy inoculum. It is a well-known fact that upon longer incubation, yeasts can make considerable growth in the absence of a given vitamin, whereas only poor or no growth will result when the incubation period is reduced. This is not a matter of slow synthesis of vitamins on the part of the cells; rather, it is a selective process whereby restricted numbers of cells with autotrophic tendencies, scattered in an overwhelming population of heterotrophic cells, find the opportunity to multiply and to establish themselves in a solution deficient with respect to a given vitamin. The heavy inoculum used by the writers contained twenty times more cells than the light inoculum, and, therefore, twenty times more chances of containing cells with autotrophic

tendencies. The principal difference between the light and the heavy inoculum is that the large numbers of cells of the latter enable the yeast to accomplish within a shorter period the same thing that a light inoculum does after a longer incubation. In addition, there is the chance factor; if a loopful of heavy inoculum contains the minimum number of cells with autotrophic tendencies, a good growth will follow; but if the inoculum happens to contain fewer than the minimum numbers the growth will be poorer. This chance factor may be responsible for most of the erratic results observed in some of the more critically deficient media, as well as for the fact that under identical conditions the heavy inocula sometimes induce good growth and sometimes poor growth. The greater the vitamin deficiency, the greater will be the erratic behavior. But once the autotrophic tendency has been developed by several passages in a solution from which one or more vitamins are omitted, yeasts grow as readily in deficient solutions as they do in the complete medium.

THE EFFECT OF A SHORTER PERIOD OF INCUBATION.—As the time of incubation was reduced, fluctuations in growth became so great and so frequent as to be utterly unpredictable. At one time, the same organisms, under the same conditions, grew remarkably well, and, at another time, poor or no growth resulted. Even in duplicate cultures one flask often grew well, the other very poorly. Such inconstant results were almost always linked with the absence of one or more growth factors. For instance, in the complete solution containing all growth factors, major fluctuations were extremely rare; when, however, pyridoxin was omitted, some fluctuations began to appear, but they reached their peak when pantothenic acid was omitted or when inositol and thiamin were left out. The increase in time of incubation tended to equalize sharp differences, and we can state that most of the results in table 1 are fairly reproducible; however, the same cannot be said about the results shown in table 2; the different replica-

TABLE 2. *The effect of growth factors on yeast as expressed by the weight in mg. of dry cells per flask after incubation of forty-eight hours at 25°C.*

tions gave such wide variations in the results as to render any sort of statistical treatment impossible. The writers found it necessary to give two averages for each treatment; one, the average of high yields, and the other that of the low yields. The less frequently appearing yields are given in parenthesis.

Table 2 shows that often the time factor determines whether or not certain exogenous substances are needed by various strains of yeasts. For instance, after seventy-two hours' incubation, the Old Process yeast was the only one that failed to grow well in the absence of thiamin; but when this period was reduced to forty-eight hours, yeasts no. 6, 7, and 8 also failed to grow well, while yeasts no. 5, 8, 9, and 10 became erratic in their behavior, sometimes growing as well as ever and sometimes being markedly reduced in growth. At seventy-two hours none of the yeasts was affected by the omission of pyridoxin, while at forty-eight hours, a number of them were restricted. Similar effects are to be seen throughout table 2.

At forty-eight hours, and in the absence of certain growth factors, many yeasts did not attain their optimum growth. Whether their erratic behavior was caused by normal fluctuations or by reversible dissociation is difficult to determine. In a later publication, the writers will show that autotrophic habits for a number of growth substances can be built up in all the strains of heterotrophic yeasts listed in this paper, so that an organism that was formerly dependent on thiamin, inositol, or pantothenic acid can now grow just as well without an exogenous supply of these substances. Since yeasts seem to possess this autotrophic habit, even though it may be masked by strong heterotrophic tendencies, it is only natural that this habit should emerge every now and then and cause the inconsistent behavior noted in table 2. Therefore, so far as conditions outlined in this paper are concerned, an incubation period of seventy-two hours is the best. While it does not eliminate fluctuations and inconsistencies alto-

gether, it reduces them to a minimum so that reasonably reproducible results may be expected.

SUMMARY

The effect of thiamin, pyridoxin, inositol, pantothenic acid, and biotin, singly and in all possible combinations, was tested on ten strains of *Saccharomyces cerevisiae*. After seventy-two hours' incubation at 25°C. only one organism was found to be dependent on thiamin, four were dependent on inositol, all ten yeasts were greatly restricted in growth when pantothenic acid was omitted, and no growth followed when biotin alone was left out. None of the yeasts were affected by lack of pyridoxin, but when thiamin and pyridoxin or thiamin and inositol were omitted, some yeasts were reduced in growth, although they were unaffected when these substances were left out one at a time. Some yeasts were unable to produce optimum growth when only two growth factors were present; some required three and some four. When the incubation period was reduced to forty-eight hours, a number of the yeasts manifested dependence on one or more growth factors which did not seem necessary when the incubation period was extended to seventy-two hours. Often the quantity of inoculum controlled growth. When 0.01 mg. of cells constituted the amount of inoculum, very poor growth was made by some yeasts; when this was increased twenty times, very good growth followed. However, in some other cases, the quantity of inoculum was without any apparent effect.

ANATOMY OF THE INFERIOR OVARY OF DARBYA¹

Frank H. Smith and Elizabeth C. Smith

THE STRUCTURE of the inferior ovary has been a much disputed question since the time of Linnaeus. A final solution of this problem would be important not only to the anatomist in interpreting the vascular structure of the flower but also to the taxonomist in determining phylogenetic relationships in the

¹ Received for publication February 28, 1942.

Published with the approval of the Monographs Publication Committee, Oregon State College, as research paper No. 58, School of Science, Department of Botany.

The authors are indebted to Professor A. J. Eames for helpful suggestions and for criticism of the manuscript. The senior author is also grateful to the Department of Botany, Cornell University, for granting him laboratory facilities and privileges as a Resident Doctor. This work was supported in part by a grant from the General Research Council, Oregon State College.

flowering plants. There are two interpretations of the inferior ovary that have been widely accepted. The first is that it is entirely floral in nature and consists of the sepals, petals and stamens fused with each other and with the ovary. The second interpretation is that the ovary is embedded in tissues of the receptacle. A third possibility that has been suggested is that the tissues surrounding the ovary may be axial in the lower portions and floral above.

The first of these theories assumes that the inferior ovary originated by the progressive fusion, phylogenetically, of the sepals, petals and stamens to each other and then to the ovary. This theory is supported by numerous investigators with anatomical evidence which is most complete and convincing.

This evidence is based on the assumption that a flower is a determinate stem bearing appendages which correspond to leaves, at least in so far as vascular traces are concerned (Eames, 1931). Evolutionary series have been demonstrated for various plant groups which indicate that adnation, or fusion of floral parts of separate whorls, results in an inferior ovary. One of the most complete of these series has been established by the work of Bonne (1928), Jackson (1934) and MacDaniels (1940). This series indicates that the floral tube or disc in most of the Rosaceae originated by fusion, first of the sepals, petals and stamens, then of the vascular bundles supplying these structures. All of the evidence thus far indicates that the inferior ovary of the Rosaceae resulted from a progressively closer union between a floral tube of this type and the ovary. On the basis of this and other series it seems evident that the inferior ovary in the Rosaceae, Ericaceae (Eames, 1931), and in various other families, is composed only of floral tissues. Another type of evidence has been used by Saunders (1925) in interpreting the structure of the ovaries in the Iridaceae and Begoniaceae. On the basis of the leafskin theory, she concluded that in these families the inferior ovary is appendicular.

The evidence for the axial or receptacular interpretation of the inferior ovary has, from the time of Payer (1857), been presented primarily by the developmental morphologist. The ontogeny of the apple flower as described by Kraus (1913) serves to illustrate this type of evidence. The various floral parts first appear as separate protuberances on the growing point. Then a zonal meristem develops behind or below these protuberances so that the ovary becomes enclosed and the developing floral parts are lifted up together above the ovary. This method of development is interpreted as an indication that the tissues formed by the zonal meristem are axial or receptacular. Adherents of the axial theory have used other types of evidence, such as abnormal flowers and gross structure of fruits, to support the theory, but as yet no really convincing anatomical evidence has been presented. For this reason the theory, though very widely accepted for the past fifty years, has been rejected by most anatomists of recent times in favor of the appendicular theory. The extreme of the axial theory is illustrated by the work of Bugnon (1926), who concluded that in the Begoniaceae the wall of the inferior ovary is composed entirely of receptacular tissues.

Bonne (1928) and Jackson (1934) concluded independently that in the genus *Rosa*, and in several other genera of the Rosaceae having floral cups, the lower portion of the floral tube is axial while the upper portion is floral in nature. Their conclusions are based primarily on the presence of recurrent traces in the lower portion of the cup. These traces are inverted, that is the xylem is located outside the phloem, and they give rise to traces to the carpels that are attached at the base of the floral tube. Thus the tube is considered to be receptacular up to ap-

proximately the point of origin of the recurrent traces, and the anatomical tip of the axis is the lowest point in the cup. Approximately the same type of structure has been described for *Calycanthus* by Smith (1928), except that the situation here is complicated by the presence of cortical bundles. These three workers have all considered the cup-shaped structure described to have arisen by invagination of the growing point. Smith (1928), Bancroft (1935) and MacDaniels (1940) have suggested the possibility that an inferior ovary that is receptacular, at least in the lower regions, might be derived by fusion of such a cup to the ovary.

Many additional papers dealing with the various interpretations of the inferior ovary have already been adequately reviewed by Bancroft (1935), by Wilson and Just (1939) and by others, so that a more complete discussion is not necessary here.

The floral anatomy of species belonging to the Santalaceae has received little attention. There are descriptions of the floral anatomy of only three genera and these descriptions are so much at variance with each other that no comparisons can be made. Since the floral anatomy of these and other genera will be described in a later publication, these papers are not discussed in detail here. Van Tieghem (1869), from a study of *Thesium* and *Osyris*, concluded that the inferior ovary in the Santalaceae is appendicular. He considered the calyx to be fused with the tricarpellary ovary, though both structures remain vascularly independent. He also concluded that the placental stalk is composed entirely of carpellary tissue and that the pedicel does not extend beyond the point of insertion of the carpel traces. Dowding (1931) described but did not illustrate the floral anatomy of two species of *Comandra* and interpreted the tissues surrounding the ovary as appendicular. As an adherent of the theory of carpel polymorphism he concluded that the ovary consisted of an outer whorl of five sterile carpels and an inner whorl of five fertile carpels, the latter of which forms the placental stalk. Schaeppi and Steindl (1937) described the anatomy of both male and female flowers of *Osyris alba*. Numerous bundles in a ring enter the floral tube of the male flower. All of these disappear near the top of the tube, except those opposite the sepals which represent combined sepal-stamen traces and separate to supply these structures. In the female flower there is an outer ring of many bundles which are interpreted as bundles of the receptacle or "Achsenmantel" and an inner ring of numerous traces interpreted as bundles of the pistil. Apparently the principal reason for considering the inner traces to belong to the ovary is that they are not present in the male flowers. In addition to these traces there are three dorsal carpellary bundles located inside the two rings of bundles and a single trace entering the placental column. It was suggested that the placental stalk may have a core of axial tissue.

The placental stalk in the Santalaceae has been compared with the free-central placenta of the Pri-

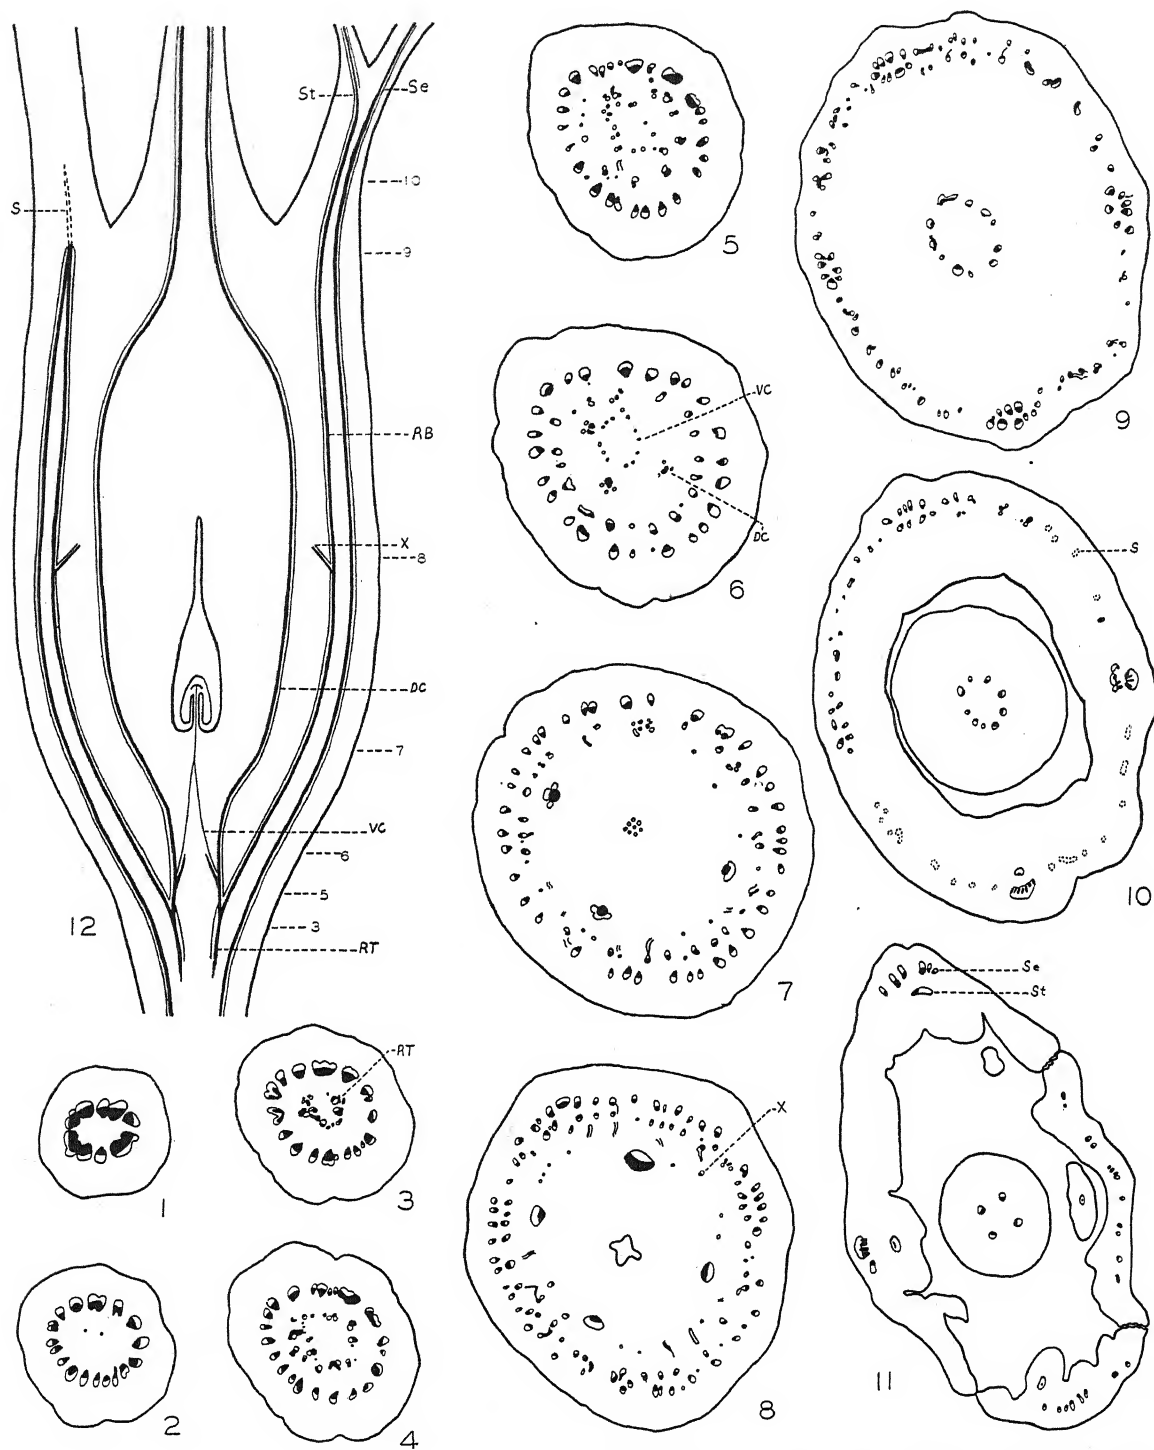

Fig. 1-12.—Fig. 1-11. Semi-diagrammatic cross sections of female flower.—Fig. 12. Reconstructed longitudinal diagram through two dorsal traces, a sepal and stamen on one side and between the sepals on the other. Sepal traces, stamen trace, dorsal and ventral carpellary traces and residual tissue are indicated by Se, St, DC, VC and RT respectively. S indicates the xylem-like sclerenchyma at base of floral tube, RB recurrent bundles. X indicates branch traces, shown cut in figure 12, which form, with dorsals, the innermost ring of bundles.

mulaceae (Engler and Prantl, 1935; Wilson and Just, 1939). In both of these families the stalk has been interpreted by various workers as consisting of either axial or floral tissues or both.

The assumption in practically all of the taxonomic literature on the Santalaceae that the inferior ovary is receptacular seems to be based principally on popular adherence to the receptacular theory, rather than on any definite anatomical evidence obtained from this family.

Santalaceae is a family of apetalous trees and shrubs occurring chiefly in the tropics. All members are generally considered to be partially parasitic on other flowering plants. *Darbya umbellulata* A. Gray (*Nestronia umbellula* Raf.) has usually four sepals with the stamens opposite the sepals and attached to them. The ovary is completely inferior with a single locule and a central placental stalk bearing 2–3 ovules at the top.

For this study flowers were obtained from herbarium sheets, boiled in water and treated overnight with 2 per cent potassium hydroxide, then dehydrated and embedded in paraffin. A very satisfactory stain was obtained by treating sections with 1 per cent chromic acid for twelve hours, rinsing in water, staining in 1 per cent aqueous safranin for twelve hours, rinsing and dehydrating, and finally treating with a dilute solution of fast green in clove oil and absolute alcohol to differentiate simultaneously the safranin and counterstain.

THE FEMALE FLOWER.—In the peduncle the vascular tissue is in the form of an almost continuous cylinder (fig. 1). At the base of the ovary this cylinder begins to separate radially into numerous strands (fig. 2). These strands swing outward and pass up the outer portion of the ovary to approximately the level where the floral tube is freed from the ovary. The number of traces in this ring of bundles is continually increased by radial separation throughout this distance (fig. 2–8). No branch traces are given off from these strands and they form few or no connecting traces among themselves. A second ring of bundles is present inside the first for the full length of the ovary. These inner traces are inverted with the xylem located outside the phloem (fig. 6–8). At approximately the level where the floral tube is freed from the ovary, the outer ring of normally oriented traces and the inner ring of inverted traces, except those in the positions of the sepals, come together in a series of anastomoses (fig. 9, and left side of fig. 12). This is the only region where there are strong connections between the two rings of bundles. At lower levels there are a few connections which are too weak and irregular to be considered as significant. Continuing upward from the connections between the two rings of bundles are a few strands of xylem-like sclerenchyma (S, fig. 10, 12) which soon disappear.

In following the bundles of the inner ring downward to the base of the ovary, it can be noted that there is a gradual reduction in number. This reduction results partly from fusion of traces and partly

from the gradual reduction in size of some traces until they disappear. The inner bundles are connected to each other at irregular intervals by small traces. Traces to the inner parts of the flower originate near the ends of the inverted traces. The relation of these branch traces to the inverted traces can best be described from the base of the flower upward. The traces of the inner ring first appear very low in the ovary and consist of a few xylem strands located in what appears to be the pith of the peduncle (fig. 2). Above this level the number of strands of the inner group increases rapidly by the appearance of new traces. Figure 3 represents a cross section taken only a short distance above the level of figure 2 and shows a ring of traces consisting of xylem only or of xylem and phloem in the inverted position. These traces soon form a complete ring which gives off branches to the inside (fig. 4, 5). There are three or occasionally four branches which are more strongly developed than the others. These are normal collateral bundles and they swing outward slightly at higher levels while the traces between them move inward (fig. 6). The traces moving inward usually consist only of phloem. Since these strands supply the ovules, they must be considered as ventral carpellary traces. If xylem is present, it is in the lower portions of the traces only and is in the normal position and not inverted as is usually the case in other families. These traces continue to move inward to form a compact strand of phloem which enters the placental stalk (fig. 7, 12). In other genera of the Santalaceae which have been studied, the placental stalk may have a large amphicribal trace, which implies a fusion of normal collateral bundles.

The larger traces, with the xylem and phloem in the typical collateral arrangement, continue to swing outward as they pass up through the ovary. At approximately the level of the top of the locule, branch traces move inward from the ring of inverted traces and take up positions between the large bundles (X, fig. 8, 12). Thus there is formed at this level a third ring of bundles, all of which in this case have the xylem and phloem normally oriented. These swing inward at the top of the ovary and form anastomoses with each other just before the style is freed (fig. 9). A varying number of traces continue upward from these anastomoses to enter the base of the style (fig. 10). The smaller ones soon disappear and only three or four traces, in the same positions as the large traces below this level, continue up into the style (fig. 11). The stigma has as many lobes as there are traces in the style, and one trace extends into the base of each lobe. Thus the large traces occupy the position of dorsal carpellary traces. This indicates that the ovary here consists of usually three but sometimes four carpels.

Directly opposite the sepals, the traces of the outer ring and the inner inverted traces do not connect at the top of the ovary as do the traces between the sepal positions. Instead they swing closer together to form what corresponds to a large compound

amphicribal bundle with the individual traces rather loosely arranged (fig. 9). However, the outer and inner traces remain distinct and at the base of the floral tube each group becomes even more compactly arranged. The inner traces opposite each sepal give rise to a single inverted trace (fig. 10). Each of these traces then swings inward to enter

trace divides radially to form the vascular bundles of the sepal (fig. 11).

THE MALE FLOWER.—The peduncle of the male flower, as of the female flower, has a compact ring of bundles which divides rapidly in radial planes to form numerous traces which enter the base of the flower. There are four lobes in the base of the cavity of the flower which probably represent four much reduced carpels (fig. 13). In some flowers a rudimentary placental stalk may also be found. A very few xylem strands may appear in the pith just below this level, but usually these are missing. Small xylem bundles may appear just inside the ring of larger traces. Some of these develop phloem on the inside to form small, inverted traces and some of the bundles in the outer ring give rise to branch traces which swing inward and rotate to assume the inverted position (fig. 13, 14). Inverted traces are more numerous and better developed opposite the positions of the sepals. Some of the small traces between the sepal positions are normally oriented and some are inverted. There is always a much smaller number of inverted traces here than in the female flower, and they are not so regularly arranged in a distinct inner ring. Just below the level where the stamen filaments begin to differentiate from the floral tube the normal and inverted traces located between the sepal-stamen complexes anastomose just as in the female flower (fig. 15). Above these anastomoses some traces continue upward for a short distance as xylem-like sclerenchyma and then disappear (fig. 16).

The stamen traces are differentiated from the inverted traces opposite each sepal (fig. 16, 17). There may be formed a single inverted trace which soon becomes amphicribal, or there may be two traces, one usually consisting of phloem only, which fuse either in the floral tube or in the base of the filament to form a single trace. In many of the flowers studied two superimposed stamens are formed opposite each sepal. Where this condition is found the stamen next to the sepal receives the larger trace and bears well developed pollen. The inner stamen trace usually consists of only a small amount of phloem, and the stamen receiving it produces aborted pollen or exists only as a staminodium.

INTERPRETATION.—The course of the principal vascular bundles in the ovary and the place of origin of the carpellary traces strongly indicate that the inferior ovary in *Darbya* is axial in nature. Both the outer ring of normal collateral bundles and the inner ring of inverted bundles must be considered as receptacular. The presence of a complete ring of inverted traces can best be explained as the result of invagination of the tip of the axis, just as has been described for *Rosa* and *Calycanthus*. This interpretation is supported by the fact that the dorsal and ventral carpellary traces arise from the inner inverted traces and not directly from the stele at the base of the ovary as would be the case if the inferior ovary were the result of extreme adnation. Also, it is to be noted that the inverted traces extend below the level at which the carpellary traces arise. The vascu-

Fig. 13-17. Semi-diagrammatic cross sections of male flower. Sepal traces, stamen traces and xylem-like sclerenchyma are indicated by St, Se and S respectively.

the base of a stamen (fig. 11). Usually before it enters the stamen the trace becomes amphicribal with a very small amount of xylem. The fact that these traces become amphicribal is probably not significant, since weak traces in flowers rather frequently show this condition. The anthers of the female flowers studied contained only aborted pollen grains.

The outer traces continue as large bundles for a short distance after the divergence of the stamen traces. At approximately the level where the sepal lobes are differentiated and the stamens freed, each

lar tissue below this level is apparently comparable to the residual tissue found in many other flowers. By residual vascular tissue is meant any vascular tissue of the stele or receptacle which may remain after all traces to floral parts have been given off. Since residual tissues represent the tips of the receptacular traces, in *Darbya*, the tip of the receptacle is directed downward. As a result the traces appear to be located in the pith of the peduncle. Thus the assump-

no traces to the disc, but, if the lobes are derived from petals, then the distal portion of the floral tube consists of fused sepals, petals and stamens.

If the interpretation of the inverted traces given here is correct, then one can agree with Van Tieghem (1869) that the placental stalk must be entirely floral. If the stalk were partly axial, the residual tissue would be directed upward inside the ventral carpellary traces. No evidence was found to substan-

Fig. 18-21.—Fig. 18-20. Longitudinal diagrams illustrating a possible method of origin of the receptacular inferior ovary of the Santalaceae.—Fig. 18. The floral cup of *Rosa* (adapted from Jackson, 1934).—Fig. 19. A hypothetical flower with a compound pistil and a floral cup which is largely receptacular.—Fig. 20. The inferior ovary of *Darbya*, which might have resulted from the fusion to the ovary of the floral cup shown in figure 19.—Fig. 21. A hypothetical inferior ovary as it might appear had it resulted from adnation. Receptacular tissues are indicated by stippling; tissues derived from fused sepals, petals and stamens by diagonal lines; the ovary wall is unshaded and ovules are omitted. Recurrent bundles, dorsal carpellary traces and residual tissue are indicated by RB, DC and RT respectively.

tion that invagination of the receptacle has occurred is supported by the presence of the inner ring of inverted bundles and the orientation of the residual tissue.

The receptacular tissue thus surrounds the ovary and extends approximately to the level where the floral tube is freed from the ovary. This is the level where the outer traces turn downward and become inverted. Possibly the base of the floral tube also is receptacular. The xylem-like sclerenchyma strands extending into the tube from the point where the traces of the outer and inner whorls join may indicate that the recurrent portions originally extended higher in the tube. As a result of fusion at the top because of proximity, the present level where the traces turn downward may be below the original level. In that case the exact proportion of the floral tube which consists of receptacular tissue would be difficult to determine. Undoubtedly the distal region of the tube consists of fused sepals and stamens. Whether the petals are also fused into this tube cannot be stated definitely, since there are no indications of petal traces. The disc in the Santalaceae has lobes alternate with the sepals. There are

tiating this idea. That the placental stalk is composed of carpellary tissues only is also supported by the fact that of the various members of the family, there are some in which the locules are separate, some in which the locules are continuous at the top but separate at the base with a corresponding reduction of the partitions, and some in which a complete loss of the partitions results in a single locule with a placental stalk attached at its base. This interpretation of the placental stalk in *Darbya* is essentially the same as that given by Dickson (1936) and Douglas (1936) for the Primulaceae.

The interpretation of the course of the stamen traces is more difficult. In both *Rosa* and *Calycanthus* the recurrent portion of the stele is the region between the points of origin of the stamen and carpellary bundles. It seems likely that this is the case in *Darbya*, but the method and point of origin of the stamen trace is obscured by extreme variation in different flowers and even in the same flower. At the level shown in figure 9 there is a group of bundles representing a combined sepal-stamen trace. The inner bundles may become very much reduced and all but one disappear; or they may fuse to form a

single trace; or there may be weak anastomoses between them, and from the anastomoses a single stamen trace may emerge which is inverted for only a short distance and then becomes amphicribal. There may also be very weak connections with the outer bundles. This latter condition is provisionally interpreted as indicating that the stamen trace originates in the base of the floral tube. This is supported to some extent by the fact that a single trace that can be definitely identified as a stamen bundle is not evident until approximately at the level where the sclerenchyma strands disappear. As suggested previously, the extent of the xylem-like sclerenchyma strands may indicate the extent of the receptacular portion of the floral tube.

It is difficult to interpret the branch traces which extend inward from the inverted bundles and assume a position between the dorsal carpellary traces (X, fig. 8, 12). There would seem to be three possible explanations: that they represent another whorl of organs, that they are median or secondary carpel traces, or that they are merely anastomosing cross branches of no morphological significance. The third possibility seems most likely because of the anomalous position, large number and small size of the traces. On the other hand, these traces consistently appear in other genera of the family and may possibly have some significance not yet understood.

The male flower is derived from a perfect flower by reduction. The dorsal and ventral carpellary traces have disappeared completely, though they are still present in the male flowers of some other genera of the Santalaceae. There is a strong tendency toward a reduction of the inverted traces. In other genera, to be described in a later publication, these traces have disappeared completely. Aside from these reductions the male flower may be interpreted as having the same structure as the female flower.

DISCUSSION.—The evidence presented here indicates that the inferior ovary in *Darbya* originated by invagination of the floral axis and subsequent fusion of the resultant cup-shaped receptacle to the ovary. Thus the outer tissues surrounding the ovary, and probably the base of the floral tube, are axial or receptacular. A complete progressive series illustrating this fusion is not available, but the situation described for *Rosa* and other genera of the Rosaceae by Bonne (1928) and Jackson (1934) and for *Calycanthus* by Smith (1928) could well represent the beginning of such a series. Figure 18 shows the structure of the floral cup of *Rosa*, with the receptacular portion indicated by stippling and the appendicular portion by diagonal lines. Progenitors of the Santalaceae may have had a floral structure similar to this. There probably followed a fusion of simple pistils in the bottom of the floral cup to form a compound pistil, and an increased invagination resulting in the hypothetical flower illustrated in figure 19. The subsequent fusion of the axial portion of the cup to the ovary would result in the situation described for *Darbya* (fig. 20). Thus the tissues surrounding the ovary would be receptacular, with re-

current traces, while the tube extending beyond the ovary would consist of axial tissue in the proximal regions and of fused floral parts in the distal regions. It must not be implied from this discussion that either the Rosaceae or the Calycanthaceae are considered to have necessarily given rise to the Santalaceae. There are several families in which cup-shaped floral tubes are found that have not yet been investigated by the floral anatomist.

The residual tissue in figures 19 and 20 is directed downward into the pith of the peduncle. Figure 21 illustrates the structure that might be found in an inferior ovary derived by adnation of floral parts. There is no indication of recurrent traces and the residual tissue is directed upward. Thus while the ovaries illustrated in figures 20 and 21 are superficially the same, the course of the vascular bundles indicates that the former is receptacular and the latter is appendicular.

While it has been held for some time that an inferior ovary may be surrounded by tissues of the receptacle, the theory has not been supported by evidence acceptable to most plant anatomists. Most of the genera used in evidence have been shown rather conclusively to have inferior ovaries which resulted from extreme adnation, and hence are appendicular in nature. For example, members of the Rosaceae have been widely used by supporters of the axial theory, but the evidence supporting the appendicular theory is most complete and convincing in this family. This evidence seems too complete not to be accepted.

If the interpretation given here for *Darbya* is correct, it then follows that both axial and appendicular inferior ovaries occur, and not only one or the other as has been rather generally assumed. There is, of course, the distinct possibility that a third type which is axial below and appendicular above may also occur. A completely inferior ovary of this type has not yet been described. It is entirely probable that receptacular inferior ovaries have developed in other dicot families just as the floral cup which is axial below and appendicular above has appeared independently in the Rosaceae and Calycanthaceae. The inferior ovary in most dicot families is undoubtedly derived by extreme adnation as has been shown particularly by Eames. There seems to be no possibility that the type of inferior ovary described here could have given rise to the type which has been interpreted as having arisen by adnation, and certainly the reverse is true. Thus the origin of the inferior ovary in each family must be determined by critical anatomical study and not by superficial comparison with some apparently related form.

Many variations in the structure of inferior ovaries of a floral nature have been described by other investigators. Obviously variations in receptacular inferior ovaries are to be expected from evolutionary changes. From a study of over sixty-five species representing more than thirty-five genera of the Santalaceae and related families, it seems likely that in *Darbya* there is a somewhat primitive condition.

There is great variation in the floral anatomy of this group and most, if not all, variations in structure can be explained as derivatives from the *Darbya* type. Without a knowledge of the relatively primitive structure of *Darbya*, it is difficult to interpret the floral anatomy of the forms in the Santalaceae studied by previous investigators, notably *Comandra*, *Thesium* and *Osyris*. A discussion of the variations in other genera will appear in a later paper (Smith and Smith, in manuscript).

SUMMARY

The vascular anatomy of both male and female flowers of *Darbya* is described.

The vascular bundles of the receptacle in the female flower extend from the peduncle to the top of the ovary before any traces to floral appendages appear. At this level some of the traces continue into the sepals. The remainder of these traces then turn downward to form an inner ring of recurrent, inverted bundles reaching to or below the base of the ovary. The dorsal and ventral carpellary traces are derived from these inverted strands at the base of the ovary. A small amount of residual vascular tissue extends downward beyond the point of origin of the carpellary traces. The inverted traces opposite the sepals give rise to the stamen traces.

The presence of recurrent inverted bundles, the downward extension of the residual tissue and the

origin of the carpellary traces from the inverted strands are interpreted as indicating that the inferior ovary here originated by invagination of the tip of the floral axis. Hence the outer tissues surrounding the ovary, containing the ascending and recurrent traces, are axial or receptacular. The basal portion of the tube extending beyond the ovary is probably composed of axial tissues while the upper portion represents fused floral parts.

Since the residual tissue is directed downward, the placental stalk is interpreted as consisting entirely of carpellary tissue.

The male flower may be interpreted in the same manner as the female flower except that the carpellary traces and many of the inverted traces have been lost by reduction.

It is suggested that anatomical evidence obtained thus far indicates that there are at least two types of inferior ovaries. One type, the result of extreme adnation, is entirely floral in nature. The other type, described here, would seem to have resulted from invagination of the floral axis followed by fusion to the ovary of the receptacular portion of the resultant cup.

CULTIVATION IN VITRO OF SMALL DATURA EMBRYOS¹

J. van Overbeek, Marie E. Conklin and A. F. Blakeslee

WHILE ATTEMPTING to induce artificial parthenogenesis by injecting physiologically active substances into unfertilized ovaries of *Datura stramonium* (16) it was realized that some of these substances might never penetrate the ovules far enough to reach the egg cell. With this in mind experiments were planned by which the development of the egg cell and the subsequent parthenogenetic embryo, should such be obtained, could take place *in vitro*. In order to accomplish this, two major steps are necessary: (a) division of the egg cell must be induced, and (b) development of the resulting embryo into a viable plant must be accomplished. It seemed obvious to try to control step (b) before attempting (a). The present paper deals with step (b), the culture of small embryos *in vitro*.

Successful culture of embryos has been reported in the literature (10, 14, 20). For a review of the literature, see LaRue (10) and White (19). The media used by the different authors vary considerably. Tukey (14) concluded that there was no appreciable difference in effect between the different salt solutions used by various workers. The concentration, too, could be varied from one to ten times without much effect. It seems clear, however, that the necessity of adding organic substances to the medium greatly depends upon the stage at which the embryos are isolated. Thus mature embryos can be grown in a strictly inorganic medium. The addition of sugar even retards their growth (14). Nearly mature embryos require sugar (10, 14). According to Tukey, the younger stages require more than the older ones. Still younger embryos require, in addition to sugar, the heat stable factors found in yeast extract or fibrin digest (10, 20). LaRue employed indoleacetic acid in low concentrations to replace yeast extract in his media.

Although the embryos successfully cultured by the authors mentioned above were often very immature, they still were isolated at a relatively advanced stage of development. LaRue (10), who successfully grew the embryos of a large number of species, makes the following statement: ". . . embryos 0.5 mm. or slightly less in length can be grown successfully . . . those of still smaller size have not yet been brought under control. . . . at a length of 0.5 mm. we may have reached a new lower threshold which will be difficult to pass." It is well to remember that the actual size of an embryo is not a measure of the stage of development in different species. Thus an embryo 0.5 mm. long of a plant having relatively large embryos, such as *Datura*, will be in a much earlier stage of development than an embryo of the same length of a plant such as *Nicotiana*, which has minute embryos.

White (20) isolated young heart-shaped embryos from *Portulaca*. These embryos grew from 0.12 to

1.84 mm. in three weeks and were not shown to be viable. A personal communication from investigators at the University of Wisconsin states that they are currently engaged in the problem of isolating and growing young embryos *in vitro*. Howard E. Heggestad (Univ. of Wisconsin, unpublished data) has succeeded in isolating embryos of *Nicotiana rustica* only nine days after pollination. Using vitamins B₁, B₂, B₆, nicotinic acid and pantothenic acid in addition to the medium used by White, he obtained viable seedlings. Lewis T. Ausherman (Univ. of Wisconsin, unpublished data) has successfully cultivated a presumably hybrid embryo of *Hordeum jubatum* × *Secale cereale*, which was taken out eleven days after pollination. The medium contained yeast extract.

Since it appeared that young embryos are less autotrophic in respect to growth factors than older ones, and since in the ovule immature embryos are nourished by the endosperm, it occurred to us that some form of endosperm should be added to the culture medium in order to supply the necessary growth factors. Coconut milk was used for this purpose. This addition made it possible to cultivate *in vitro* embryos of *Datura stramonium* so immature that they were of small heart shape and only 0.15 mm. in length (the embryo in the mature seed is approximately 6 mm. long). In many cases such embryos increased in length from 0.15 mm. to 6.0 or even 8.0 mm. after seven days of cultivation *in vitro*. They subsequently developed, by proper treatment, into normal plants.

NORMAL DEVELOPMENT OF DATURA EMBRYOS.—In order to understand the development of embryos *in vitro*, a brief outline of the normal development of *Datura* embryos follows. Detailed work by Satina and Blakeslee on the histology of the normal development of *Datura stramonium* is in progress. About thirty hours after pollination, fusion of the gametes occurs. Nine to fourteen days following pollination, the embryo has developed into an undifferentiated knob-like structure attached with the suspensor at the micropylar end of the embryo sac. According to the terminology of Souèges, the embryo at this stage is called a *proembryo* because it shows axial symmetry. At a later stage the apical part flattens out, due to formation of the primordia of the cotyledons. When they start to grow out, a *heart-shaped* embryo results. Such heart-shaped embryos may be found between ten and sixteen days after pollination. Embryos in this particular stage of development, varying between 0.15 and 0.5 mm. in length, were extensively used in these investigations. When the embryo reaches a length of 1 mm. or over it assumes a *torpedo shape*. At this stage the cotyledons are about half as long as the total embryo. A root cap and also the meristem of the epicotyl has been initiated. When the embryo is about 2 mm. long, it begins to curve. At still later stages it becomes folded inside the seed, and at maturity is about 6 mm. long.

¹ Received for publication February 23, 1942.

We wish to express our appreciation to Mr. George Risman for his skillful assistance.

TECHNIQUE OF ISOLATING EMBRYOS.—The embryos were grown under aseptic conditions. The capsules of field-grown plants were dipped in alcohol, soaked in 0.1 per cent HgCl_2 for a few minutes, rinsed with sterile water and cut in a sterile Petri dish. The ovules were removed and held between two glass slides which were sterilized immediately before using by dipping in alcohol and flaming. Next the ovules were cut longitudinally by drawing a flamed razor blade between the slides. It was found that by using the blade while it was still warm cutting was facilitated. When proembryos or heart-shaped embryos

less satisfactory than low percentage agar media. This is in agreement with Tukey (14) and LaRue (10). Tukey, however, claimed better results with embryos placed on the surface. This disagreement with our observations might be explained on the basis of a difference in stage of development of the embryo at the time of isolation. Tukey's embryos were more mature. White (22) reported differentiation in growth of callus tissue placed below the surface of a liquid medium.

MEDIA AND RESULTS.—Embryos in stages ranging from medium curved (fig. 1a) to mature embryos

Fig. 1. Effect of different media on growth *in vitro* of *2n* *Datura stramonium* embryos. Initial size 2 mm. fourteen days after pollination. Photographed after eight days in incubator at 25°C. and an additional nine days in the greenhouse. Embryos shown came from the same capsule. (a) On plain agar—no growth; (b) agar with mineral salts and sugar only—no cotyledons, not viable; (c) on medium as (b) but with mixture of growth factors added (see text)—complete, viable seedling; (d) on medium similar to (c) but with non-autoclaved coconut milk added—no roots, enlarged cotyledons and hypocotyl. Scale in mm.

were to be isolated, the ovules were cut into almost equal parts, but when larger embryos were to be removed they were cut into unequal parts so as to avoid damage to the embryo. If the ovule was correctly cut, the embryo could be seen in one of the cut parts of the ovule when inspected under the preparation microscope. The embryos could be removed without injury under the preparation microscope by means of sterile needles. Fluorescent lights (two 40-watt bulbs) were used for illumination because the heat of ordinary incandescent lights caused the embryos to dry out too rapidly. The embryos were transferred to sterile vials (35×10 mm.) containing $\frac{3}{4}$ cc. of an agar medium described below. The embryos were placed below the surface of the medium, because they grew more uniformly this way than when placed at the surface. The cultures were kept in an incubator at $25^{\circ} \pm 1^{\circ}\text{C}$. Some cultures were transferred to the greenhouse after they had been in the incubator for approximately one week. Liquid media were found

usually could be grown in a medium consisting of 1 per cent agar (in later experiments 0.8 per cent was used), 1 per cent dextrose and mineral salts mixed according to Tukey (14, 15). When kept in dim light, a root, the hypocotyl and small cotyledons usually developed and viable seedlings were obtained. Embryos at "torpedo" stage developed a root and a hypocotyl but usually failed to develop cotyledons on this medium (fig. 1b). In order to induce better growth, such young embryos were grown on a medium to which in addition to the ingredients already mentioned, a mixture of growth factors was added.² This mixture was arbitrarily made up and, because it proved effective, was maintained throughout this investigation. It is highly probable that some of the compounds are not essential and that the essential ones are not present at optimal concentra-

² Concentrations in mg. per liter; glycine 3.0, thiamin 0.15, ascorbic acid 20.0, nicotinic acid 1.0, vitamin B₆ 0.2, adenine 0.2, succinic acid 25.0, pantothenic acid 0.5.

tions. Glycine was chosen because according to White (21, 23) it promotes growth of tissue cultures. There is, however, considerable disagreement as to its essentiality for root growth (5, 12, 8). Thiamin is a well-known growth factor for embryos (9, 4) and roots growing *in vitro* (3, 11). Ascorbic acid is also a growth factor for plants (6). Nicotinic acid and vitamin B₆ are recognized as growth factors for some roots (1) including those of *Datura* (5). Adenine is a leaf growth factor (2). Succinic acid, ac-

cording to Thimann (13), is essential for auxin-controlled respiration. In this medium embryos, when isolated at torpedo stage and kept in dim light can be made to develop into viable seedlings (fig. 1c) with well-developed cotyledons. However, when the embryos were below 0.5 mm. in length when isolated, they failed to develop in this medium (fig. 6c). This agrees with the limit set by LaRue (see above).

In order to promote the growth of embryos below 0.5 mm. in length, a new medium was devised. Since

Fig. 2-5.—Fig. 2 (upper left). Growth of $2n$ embryos, initially heart-shaped, 0.2 mm. largest dimension, isolated ten days after pollination. Photographed after eight days in incubator at 25°C. and an additional five days in the greenhouse. (a) On agar medium containing sugar, mineral salts and vitamin mixture; (b, c and d) three tests made with a medium similar to (a) to which non-autoclaved coconut milk from three different coconuts was added. Scale in mm. Note branched and lobed cotyledons in some cases.—Fig. 3 (upper right). Test similar to figure 2. The heart-shaped embryos initially 0.25 mm., isolated ten days after pollination. Photographed after eight days at 25°C. (a) On medium similar to figure 2a—no growth; (b, c, d) three tests made with a medium similar to (a) to which non-autoclaved coconut milk from three different coconuts was added—growth and differentiation of hypocotyl and cotyledons.—Fig. 4 (lower left). Growth of $4n$ embryos, initially 0.3 mm. greatest dimension, heart-shaped and isolated eleven days after pollination. Photographed after eleven days at 25°C. (a) On agar medium containing mineral salts, sugar and vitamin mixture—no growth; (b) on same medium to which autoclaved coconut milk was added—callus-type growth; (c) on medium same as 2a to which non-autoclaved coconut milk was added—growth and differentiation of hypocotyl and cotyledons.—Fig. 5 (lower right). Growth of $2n$ embryos initially pro-embryo to very small heart-shaped 0.14 in diameter, isolated fourteen days after pollination: (a) indicates original size, (b) photographed after twelve days at 25°C. on medium similar to figure 4c—growth and differentiation of hypocotyl and cotyledons. Note plumule development.

Fig. 6. Growth curves of individual embryos isolated when heart-shaped, twelve days after pollination. Ordinate: length in mm. Abscissa: days of cultivation at 25°C. (a) Agar medium containing sugar, mineral salts, vitamin mixture (see text) and non-autoclaved coconut milk; (b) similar to (a) with vitamin mixture omitted; (c) similar to (a) with coconut milk omitted.

in nature embryos are nourished by the endosperm, a natural endosperm in the form of coconut milk was added to the medium already containing agar, dextrose, inorganic salts and the mixture of physiologically active substances mentioned above. The coconut milk was removed under sterile conditions by pipetting and stored in Erlenmeyer flasks. The activity of the coconut milk stored in this manner in the refrigerator was maintained in most cases for at least several weeks. When one part of sterile non-autoclaved coconut milk was mixed with approximately two parts of the still-warm agar medium, heart-shaped embryos as small as .15 mm.³ in largest dimension could be grown (see table 1). The rate of growth amounted to several hundred times increase in volume per week (17). In one case even radially symmetrical embryos were grown (fig. 5), although later attempts to repeat this failed. Autoclaved coconut milk was not effective, but occasionally supported a callus-like type of growth without much differentiation (fig. 4b).

Figure 6 shows the growth in length of heart-shaped embryos which were between 0.2 and 0.5 mm. long when removed from the ovules. When grown in the complete medium (fig. 6a) containing both the mixture of growth factors and non-autoclaved coconut milk,⁴ noticeable growth occurred within two

³ Since the measurements of the embryos immersed in agar were made through the curved glass wall of the culture vial, the actual length is slightly less.

⁴ The coconut milk used in this particular experiment had been stored in the refrigerator for ten days.

TABLE 1. Length (in mm.) of small heart-shaped *Datura* embryos, which were 0.15 mm. in length when isolated, grown on a medium containing 0.2 cc. of non-autoclaved coconut milk per 0.75 cc. of agar medium, at 25°C. Data selected from material of two large experiments. Controls grown on medium without coconut milk shrank slightly.

days, and after six days some of the embryos were 5 mm. long and 0.8 mm. in diameter. It should be noted that in figure 6 the growth curves of individual embryos are represented. All embryos were removed from ovules contained in one and the same capsule. It is clear that even in the complete medium not all embryos developed. Three of the nine embryos of figure 6a failed to grow. This failure is not associated with a possible small initial size of the embryo, be-

cause the three smallest embryos, which were respectively 0.2, 0.25 and 0.25 mm. long, gave the largest embryos after six days of cultivation (respectively, 4.8, 4.2 and 5.4 mm. in length and 0.8, 0.6 and 0.8 mm. in diameter). When the mixture of growth factors was omitted from the medium, but the coconut milk maintained (fig. 6b), the embryos grew, but not as much as in the complete medium. When only coconut milk was omitted from the complete medium (fig. 6c), no growth resulted with these small-sized embryos. Similar results are shown in figures 2, 3, 4 and 5.

DISCUSSION.—A feature of the embryos grown in media containing coconut milk is the absence of roots. This is probably due to a root inhibitor in the coconut milk. This inhibitor appears to be heat stable, because, when older embryos were grown on media containing autoclaved coconut milk, root development was markedly suppressed. It is possible that the root inhibitor is related to auxin, since, despite the root suppression, growth of the hypocotyl is not inhibited by it. It is known that auxin inhibits root growth in concentrations which still permit stem growth (18). Root growth could be induced by transferring embryos which had been grown for approximately one week on a medium containing coconut milk, to a medium free of it. When placed in dim light, viable seedlings resulted which grew in soil. Embryos started on a medium such as used in the test represented in figure 6b often produced better roots than those started in the complete medium. In the course of investigations on the chemistry of the growth factors of the coconut milk,⁵ several other methods have been discovered which produced roots on the embryos without transferring. They will be reported on later.

It is interesting to note that in the normal development of coconuts the roots of the germinating coconut embryo remain in the fibrous outer shell but do not penetrate into the milk as one might expect on the basis of the position of the embryo in the seed (7). It seems likely that the root inhibitor in the milk is responsible for the failure of the roots to grow into the milk.

Another feature of the medium containing non-autoclaved coconut milk is the development of large, thick cotyledons (fig. 1d), which often show lobe formation and branching (fig. 2b, c, d). In this connection it is noteworthy that in germinating coconut embryos the cotyledons penetrate into the milk and develop into a large bulbous tissue. Again the same substances present in the milk that stimulate cotyledons of the *Datura* embryos to such a great development (fig. 1d) may also be responsible for the development of the coconut cotyledons. Often in the *Datura* experiments the plumule developed prematurely (fig. 5b).

In an attempt to simplify the technique by placing halved ovules containing the young embryo in the nutrient medium, it was found that such embryos did

not grow, whereas similar embryos, when completely isolated, grew well in the medium as shown above. A considerable callus formation usually took place at the cut surface of such halved ovules.

From the data presented one could tentatively conclude that at least three factors or groups of factors present in coconut milk affect the growth of embryos *in vitro*: (1) a thermolabile factor which causes the embryos to grow rapidly and to differentiate. In its impure state, this factor is heat stable to only about 50°C.;⁵ (2) a heat stable factor which causes a callus-like growth but no differentiation; and (3) a factor which appears to be heat stable which inhibits root development. From the fact that coconut endosperm affects the growth of *Datura* embryos one could conclude that the growth factors involved may be widespread in occurrence and of fundamental significance in the growth process of plants.

SUMMARY

Isolated heart-shaped *Datura stramonium* embryos as small as 0.15 to 0.2 mm. and as young as ten days after pollination were grown *in vitro* under aseptic conditions in an agar medium containing dextrose, mineral salts, a mixture of physiologically active substances and non-autoclaved coconut milk. At 25°C. the length of the embryos may increase from 0.2 mm. to 5 mm. within six days, corresponding to a 500 times increase in volume (fig. 6a). In one case radially symmetrical embryos 0.14 mm. in diameter grew to 10 mm. in length in ten days and increased in volume 8,000 times (fig. 5). Viable seedlings could be obtained by transferring after one week to a medium without coconut milk, which allowed the roots to develop.

It appears that in coconut milk at least three factors or complexes are present which affect the growth of embryos: (1) a thermolabile factor causing both growth and differentiation (fig. 2, 3, 5); (2) a heat stable factor causing in some cases a callus-like growth but no differentiation (fig. 4b); and (3) a heat stable factor which inhibits root growth and which may be related to auxin.

DRAWING GUIDE FOR ZINC ETCHINGS

Letters, lines, and dots in relation to reduction for the printed page. Top—Reduction to 1/4. Middle—Reduction to 1/2. Bottom—Original size.

Reprinted by permission of the authors from: RIKER, A. J., and REENNA S. RIKER. 1936. *Introduction to research on plant diseases*. 117 p. Published by the Authors, Department of Plant Pathology, University of Wisconsin, Madison, W's.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

CYTOPLASMIC INCLUSIONS IN THE GLANDULAR EPITHELIUM OF THE SCUTELLUM OF *TRITICUM SATIVUM* AND *SECALE CEREALE*¹

John A. O'Brien, Jr.

ALTHOUGH THERE have been many attempts in recent years to determine the structural basis of secretion in animal gland cells, there has been very little investigation of the gland cells of plants in which modern cytological techniques were employed. While there is some agreement among biologists as to the rôles of the Golgi apparatus and mitochondria in relation to the secretory activity of animal cells, the very existence of the Golgi material in plants is questioned, and there is as yet no agreement as to the possible homologue of the apparatus in the vegetable cell. The mitochondria in plants have also been assigned a number of different functions, so it becomes highly desirable that plant gland cells be investigated further. Previous research on these cells has been confined principally to the proteolytic-enzyme-secreting cells of the carnivorous plants and to the epithelial gland cells of the scutellum of the grains. The present work is limited to an investigation of the morphological changes occurring within the cells of the latter, particularly with respect to the mitochondria. It is to be recalled that the cells in question have a two-fold function, absorption and secretion, a distinction that the majority of previous workers failed to make.

Plant physiologists early advanced evidence that the scutellar epithelial cells were gland cells, although the endosperm from which the embryo had been removed could itself digest its stored starch. The glandular nature of these cells has been generally accepted and is supported by more recent investigations of the physiology of germinating grains (Grünfeld, 1926; Schander, 1934).

Cytoplasmic granules have been reported in the epithelial cells of the scutellum of barley by Brown and Morris (1890) and of corn by Torrey (1902) and Reed (1904). These investigators suggested, directly or indirectly, a similarity between the granules and the zymogen granules of animal gland cells. Guilliermond (1908) observed an increase in basophilic granules in the epithelial cells of rye, barley, maize and wheat during germination and suggested a possible correlation between their presence and secretory activity. He later (1933) maintained, however, that the secretion of diastase produced no appreciable cytological alterations in the epithelial cells, and that the basophilic granules were merely mitochondria altered by fixation. Horning and Petrie

(1927) observed an increase in the number of mitochondria by division in the epithelial cells of maize, wheat and barley, both in fixed cells and in living cells stained with Janus green. On the theory that mitochondria are the site of enzyme synthesis, they made the interesting suggestion that these bodies with the associated enzymes actually migrate from the epithelial cells into the endosperm, where, in contact with the starch grains, they disappear as the enzymes are liberated. As the identification of mitochondria in living plant cells by vital staining is very uncertain and as Janus green, together with most basic dyes, stains certain types of plant vacuoles (Bailey and Zirkle, 1931), the nature of these migratory inclusions seems somewhat uncertain. Newcomer (1938) demonstrated the presence of polymorphic and filamentous mitochondria in the epithelial cells of germinating maize but could find no evidence of their migration from the cell.

MATERIALS AND METHODS.—The plants investigated were *Triticum sativum* and *Secale cereale*. The grains were germinated in the dark on moist filter paper in Petri dishes. Since no attempt was made to keep the germinating grains at a constant temperature, the several stages of germination were identified by relative lengths of the radicle and the shoot rather than by the length of time which had elapsed since the germination was initiated. Observations were confined to fixed sections.

Zirkle (1929) suggested the use of the term mitochondria to include all those small cytoplasmic inclusions preserved by bichromates on the basic side of pH 4.2–5.2 and destroyed by more acid fixatives and by mixtures of bichromates and acetates. The pH range has since been narrowed to 4.8–5.2. This definition, used frequently in the literature, includes plastid primordia. In the epithelial cells under investigation, however, those inclusions which were observed to give rise to plastids are sufficiently differentiated in size and shape from the non-plastid forming mitochondria to warrant their designation as plastid primordia. In the present investigation, therefore, the term mitochondria is limited to those bodies included in the above definition which were not observed to give rise to plastids. The term plastid is applied only to those inclusions containing starch. The bichromate fixative used was Zirkle's (1934) modification of Erliki's potassium bichromate-copper sulfate mixture, composed of 1.25 gm. $K_2Cr_2O_7$; 1.25 gm. $(NH_4)_2Cr_2O_7$; 1.00 gm. $CuSO_4$ and 200.00 gm. H_2O . To this mixture enough pyridine was added to make a 0.50 per cent solution. The resulting precipitate was allowed to settle before the fixative was used.

¹ Received for publication January 13, 1942.

The author wishes to express his sincere gratitude to Professor Conway Zirkle for his suggestions and helpful criticisms during the course of this investigation and to Professors J. R. Schramm and William Seifriz for criticism of the manuscript. Part of this investigation was made during the tenure of a Harrison Fellowship in botany at the University of Pennsylvania.

For observations on the vacuole and its contents as well as the mitochondria, the above mixture, to which was added, in place of pyridine, 40 per cent formaldehyde to make 4 per cent, was employed. For the same purpose Bensley's (1910) formalin-bichromate-sublimite mixture was used in the following proportions: 2.50 gm. $K_2Cr_2O_7$; 5.00 gm. $HgCl_2$; 90.00 gm. H_2O . To this solution was added 40 per cent formaldehyde to make 4 per cent. After fixation in these last two solutions, the mitochondria did not retain the stain in the degree that they did after treatment in modified Erliki's-pyridine mixture, and in many sections they could not be observed. For

Fig. 1. Longitudinal sections of epithelial cells in grains of *Triticum* at successive stages of germination showing changes in cell size and shape; a, cells in resting grain; b, cells in germinating grain, the shoot of which has lengthened to 30 mm.; c, cells in grain with shoot 75 mm. in length; d, cells at end of germination; shoot 150 mm. in length. Irregular shape and lateral separation are evident. All figures $\times 300$.

preserving the vacuole and its contents alone, a chromic sulfate-formalin mixture was used in the following proportions: 5 gm. $Cr_2(SO_4)_3 \cdot 15 H_2O$; 0.5 gm. CuO ; 90.00 gm. H_2O . To this solution was added 40 per cent formaldehyde to make 4 per cent (Zirkle, 1928).

Hardened endosperm made sectioning difficult. The young plants with scutella intact were, therefore, removed from the grain before fixation. The specimens were placed in the fixatives for forty-eight hours, after which they were washed in water and dehydrated in butyl alcohol (Zirkle, 1930) and embedded in paraffin. Sections were usually cut 5 micra in thickness. Heidenhain's iron-alum hematoxylin was the only stain employed.

Illustrations were made with the aid of a camera lucida.

CYTOPLASM OF THE EPITHELIAL CELLS AND ITS INCLUSIONS.—As germination progresses, there is a gradual increase in the length of the epithelial cells of the scutellum accompanied by a separation of the lateral walls as was first described by Brown and Morris (1890) and substantiated by later workers (fig. 1). Greater surface exposure is thereby provided for secretion and absorption, the specialized functions of these cells. In both rye and wheat, a greater lengthening occurs in the cells in the anterior or shoot region of the scutellum. Since the embryo is situated in the posterior portion of the grain, that part of the epithelial layer opposite the radicle is regarded as the posterior region and that part opposite the plumule, the anterior region. In the later

stages, when the endosperm is approaching depletion, the epithelial cells appear as elongated, irregular projections, many of which are almost entirely separated from all adjoining cells (fig. 1d). The distal end assumes a variable form, sometimes developing what Horning and Petrie (1927) described as hypha-like protuberances (fig. 1d). It is to be noted that the lengthening of cells could be correlated only broadly with any particular stage in the germination process. Thus, occasionally, the epithelial cells of one grain are longer and display more advanced morphological changes than the epithelial cells of another grain with a shoot of equal length.

RESTING STAGE.—Aleurone grains.—In the resting stage of rye and wheat grains, the short, closely placed epithelial cells contain a very dense and usually non-vacuolate cytoplasm. All the fixatives used disclose the presence of numerous, small, clearly delineated bodies dispersed in the cytoplasm (fig. 2). These structures stain lightly and irregularly and probably represent a fixation image of the aleurone grains which Guilliermond (1908) demonstrated to be present in the cells. The fixatives used also disclose in the scutellar parenchyma of wheat and rye larger aleurone grains similar to the grains in the epithelial layer. Occasionally a few epithelial cells in a section contain grains stained intensely. More generally, however, the stain is retained only slightly so that in many cases, particularly after fixation in Bensley's mixture or chromic sulfate-formalin fixative, an internal differentiation is observed in which a dark periphery inclosing non-stained areas can be discerned. Guilliermond identified the darkly staining portion as the amorphous protein of the aleurone grain while the non-staining areas represent globoids inclosed within the grain.

Mitochondria.—The presence of mitochondria in the epithelial cells cannot be demonstrated with any certainty during the resting stage. The dense cytoplasm and the dispersion of numerous small aleurone grains make delineation of any such bodies difficult. Horning and Petrie (1927) and Newcomer (1938) reported the presence of granular mitochondria in the resting stage of maize, the former after using an osmo-chromic fixative, the latter after fixing in modified Erliki's solution. That most of the inclusions represented in figure 2 are not mitochondria can be demonstrated readily by fixing the cells in a solution which will not preserve mitochondria. For this purpose a mixture of 0.5 per cent chromic acid and 1 per cent acetic acid was used. In the cells of a number of specimens thus fixed the inclusions were preserved as deeply staining discrete bodies, thus further substantiating the observation of Guilliermond (1908) that the bodies are aleurone grains. Undoubtedly they are not mitochondria. Since none of the fixatives used preserved the mitochondria, yet destroyed the aleurone grains, it cannot be stated definitely that mitochondria are present during the resting stage. That they are present, however, but masked by the aleurone grains can be assumed, since their occurrence can be demonstrated in the wheat

grain before the resting stage while the grain is still developing on the wheat plant.²

During the initial hours of germination, while the grain is swelling, little change is noted in the epithelial cells. Numerous aleurone grains are still preserved intact. Mitochondria are still not discernible, although Guilliermond reported the presence of basophilic granules from the first hours of germination.

STAGE I.—*Vacuoles*.—After germination continues for twenty-four hours, at which time the radicle has usually just broken through the outer coverings of the grain, marked changes occur in the epithelial cells. In numerous cells, small round or irregularly shaped vacuoles dispersed throughout the cytoplasm are evident, many of which enclose one or several small darkly staining granules (fig. 3). Guilliermond demonstrated the formation of vacuoles through the swelling and dissolution of the aleurone grains. The dark granules in the vacuoles at this stage are probably the fixation images of the precipitated remains of the aleurone grain protein. In some specimens at this stage a number of cells still retain intact numerous aleurone grains.

***Plastids and mitochondria*.**—The most striking difference brought about after twenty-four hours germination is the presence of numerous inclusions which are preserved by the mitochondrial fixatives. At this and the following stage, two types of inclusion are discernible. Representing the first type are many large, usually rod-shaped bodies dispersed throughout the cytoplasm (fig. 4). Often these inclusions are knobbed structures. Rather than rod-shaped, they sometimes appear rounded off and shortened (fig. 4). Frequently they contain round, optically clear vesicles which are often present at the end of the rod (fig. 4). At a later stage (IV), to be referred to, the vesicles in these inclusions can be identified as starch grains by means of a polarizing microscope. Thus these bodies are plastid primordia or, if starch is present, plastids. The presence of such structures should be expected, for Guilliermond (1908) and Toole (1924) reported the presence of starch in the epithelial cells during germination.

Representing the second type of inclusion present at this stage is a profusion of minute granular mitochondria (fig. 4). These bodies which are dispersed throughout the cytoplasm were never observed to develop into plastids.

Neither of these two types of inclusion shows any orientation which would suggest its passage through the end wall of the cell as reported for mitochondria in the epithelial cells by Horning and Petrie (1927). Instead they are present in equal numbers in all parts of the cytoplasm.

All of the above mentioned inclusions retain the stain deeply after fixation in modified Erliki's-pyridine mixture. They stain only lightly when Bensley's solution is used; moreover, the plastid primordia and

plastids are much contracted after fixation in this mixture (fig. 16).

STAGE II.—*Vacuoles*.—As germination continues and the shoots reach a length of 4 to 5 mm., the number of small vacuoles increases. In the majority of cells larger vacuoles appear, particularly in the basal part of the cell, due probably to the swelling and coalescing of smaller ones, as the number of vacuoles per cell decreases (fig. 5, 6). In the distal part of the cells the vacuoles, without undergoing any great increase in size, assume a tortuous, canalicular form, many of which are orientated parallel to the longitudinal axis of the cell (fig. 5, 6). In general, then, the cytoplasm appears more dense in the distal part of the cell than in the basal part. As the cytoplasm in these cells has been observed in rapid cyclosis, perhaps the shape of the vacuoles indicates only the condition of cytoplasmic movement at the moment of fixation and not some secretory function of the vacuole. The precipitated remains of the aleurone grains are still evident in some cells (fig. 5, 6).

As previously indicated in stage I, there is no marked change in the mitochondrial or plastid complex at this stage (fig. 4).

STAGE III.—*Vacuoles*.—As the shoots increase from 5 to 15 mm. in length, the cells become more vacuolate, large vacuoles forming in both the basal and distal parts of the cell as a result of further increase in size and coalescence. Often a single large vacuole, surrounded by a thin layer of peripheral cytoplasm, is formed in the extreme basal region. This vacuole, in the fixed cell, is usually empty (fig. 7) or contains, at most, a few strands of precipitated vacuolar material. While many specimens at this stage contain numerous cells with the empty basal vacuole, its presence is more characteristic of the next and later stages. In the enlarged vacuoles in the distal region there is contained a vacuolar material which is preserved usually as a lightly staining, homogeneous mass (fig. 7). This substance usually completely fills the vacuole so that often it cannot be delineated readily from the surrounding cytoplasm, especially after fixation in modified Erliki's-formalin or Bensley's mixture. While all the fixatives used preserve the vacuolar contents, in many specimens, particularly after fixation in chromium sulfate-formalin mixture, the vacuolar material is precipitated in irregular clumps (fig. 8), although an occasional cell in the same section will have vacuoles containing the homogeneous precipitate (fig. 9). In some cells, the basal vacuoles also contain the precipitated material (fig. 8). In vacuoles of many cells, usually one or occasionally two or three darkly staining, spherical granules are also preserved. They either occur free in the vacuole (fig. 12, 13) or are embedded in the non-staining vacuolar material, if both are present in the same vacuole (fig. 23, 25). Although preserved by all the fixatives here used, they are particularly evident after fixation in modified Erliki's-formalin mixture. Guilliermond (1908) reported the retention, in the earlier stages of germination, of some of the aleurone grain protein which

² No attempt was made to differentiate plastid primordia from non-plastid-forming mitochondria before germination had begun.

Fig. 2-7.—Fig. 2. Longitudinal section of epithelial cells in resting grain of *Triticum* fixed in modified Erliki's-formalin showing numerous small aleurone grains dispersed in the cytoplasm.—Fig. 3. Epithelial cells in germinating grain of *Triticum*. The radicle is just beginning to break through the outer grain covering. Modified Erliki's-formalin. Numerous small vacuoles formed from the dissolution of aleurone grains are evident. Some vacuoles still contain remnants of undissolved aleurone grain protein.—Fig. 4. *Secale*. Shoot 5 mm. Modified Erliki's-pyridine. Numerous large,

fused as the vacuoles coalesced. That these granules are of aleurone grain origin is doubtful, since they persist throughout the germination process and, at times, appear somewhat enlarged (fig. 10, 23, 25, 27, 31).

In a few specimens, fixation, particularly in modified Erliki's-formalin mixture, renders the cytoplasm and vacuolar material so homogeneous that the cell appears non-vacuolate except for the empty basal vacuole if it is present. That the distal region is vacuolate, however, can be concluded, since there is often present the above described, deeply staining, vacuolar granule. In such cases, the granule appears to be embedded in undifferentiated cytoplasm. Since so many other specimens show it to be contained in the vacuole, it can be concluded that the granule in this case is embedded in homogeneous vacuolar material which cannot be distinguished from the surrounding cytoplasm.

The mitochondrial and plastid elements dispersed in the cytoplasm retain the same general characteristics they displayed in stages I and II. In addition to the forms of plastids previously described, there are present occasionally small clusters of non-staining spheres held together in a thin, deeply staining matrix (fig. 11). The non-staining spheres are evidently starch grains.

Mitochondrial grouping.—In a number of cells at this stage, there is discerned, usually distad to the nucleus, a peculiar solitary grouping of large mitochondrial bodies. The attenuated elements extend in all directions from the center of a lightly staining, homogeneous mass and terminate in swollen head portions (fig. 11). The chance grouping of freely dispersed plastid primordia often renders identification of this structure difficult during this stage. However, in a number of cells, it is differentiated sufficiently from the dispersed plastid primordia to make identification definite. The difficulty in differentiating the structure from the plastid primordia occurring free in the cytoplasm may explain the failure to observe it in earlier stages. The grouping, to be more fully described, is better delineated in the following stage.

In many specimens, the cells have lengthened considerably during this stage and lateral separation, particularly of those cells in the anterior region of the layer, is evident.

Stage IV.—Vacuoles.—As the shoot increases in length from 15 to 30 mm., the various cytoplasmic inclusions become more distinct. Increased vacuolization characterizes the majority of cells. If the nucleus is basal, a vacuole extends from the nucleus to the distal end of the cell; if central, vacuoles are present in both the basal and distal regions (fig. 10, 16). The homogeneous vacuolar precipitate, de-

scribed in stage III, is present in the cells of practically all specimens as a lightly staining mass which completely fills the vacuole (fig. 10, 16). This material is preserved by all the cytoplasmic fixatives used. While in any one specimen this precipitate characterizes the majority of cells, yet some cells contain practically empty vacuoles, housing at most a few irregular clumps of vacuolar material. As noted in stage III, many cells contain an empty basal vacuole, especially towards the end of this stage. In such cells, the homogeneous vacuolar precipitate often extends to the very limits of the clear vacuole. In many cases the granular cytoplasm is not visible between the two areas, so that they appear contiguous (fig. 16). In some cells the presence of a thin membrane is discernible (fig. 10, middle cell). At other times a definite zone of granular cytoplasm separates the two regions. Occasionally the homogeneous material extends throughout the entire length of the cell, even into the basal region (fig. 10). Frequently the homogeneous area is interrupted by the presence of a small, clear vacuole (fig. 10, 21) in which the spherical granule, noted in stage III, is often retained. Guilliermond (1908) reported the presence of a substance which stained in a diffuse manner in the vacuoles in the distal part of the cells from the fifth day until the end of germination. After an examination of his figures, it is to be concluded that the diffusely staining vacuolar material and the homogeneously precipitated material here reported are the same substance. As noted by Guilliermond (1908), this material persists until the end of germination, at which time the vacuoles appear empty. As indicated in stage III, a few specimens, notably those fixed in chromic sulfate-formalin, disclose the presence of only a small number of cells containing the homogeneous precipitate; in the majority of cells, the vacuoles are open, elongated cavities which stretch throughout the length of the cell and contain the precipitated vacuolar material in irregular clumps (fig. 12, 13). Other specimens fixed in the same killing fluids contain the homogeneous material in the majority of cells (fig. 10). The homogeneous material should be regarded as vacuolar and not as a non-granular portion of the cytoplasm, for the region occupied by this material is clearly vacuolar in earlier stages (fig. 3, 5, 6), and even in this stage it appears as a vacuole in certain cells, particularly after fixation in chromic sulfate-formalin. Some evidence to the contrary should be noted, however. In some instances, the material itself seems to contain vacuoles which appear empty when preserved by the usual cytoplasmic fixation (fig. 10, 21).

Mitochondria and plastids.—As in the previous stage, a profusion of the minute granular mitochondria is dispersed throughout the cytoplasm (fig. 14—

deeply staining plastid primordia are evident. The vesiculated forms are plastids. Small granular mitochondria are dispersed throughout the cytoplasm.—Fig. 5-6. *Secale*. Shoot 5 mm. Modified Erliki's-formalin. In the basal part of the cell, vacuoles are enlarging and coalescing. Note the presence of canalicular vacuoles in the distal part. Aleurone grain protein remnants are still evident.—Fig. 7. *Triticum*. Shoot 11 mm. Modified Erliki's-formalin. Enlarged vacuoles in the distal region of the cell are filled with a homogeneous precipitate. Large, empty basal vacuoles are evident. Note lightly staining plastid primordia and plastids. All figures $\times 1,550$.

19). Occasionally small filamentous mitochondria are present among the granular forms (fig. 17, 18). The plastid complex, in general, appears as previously described. The plastid primordia are usually present in the form of homogeneous rods (fig. 17, 19, 20, 21). The plastid assumes a variety of forms, frequently being preserved as a rod containing one or several small, optically clear vesicles either at the end of the rod or strung along its length (fig. 14-16, 18-19). Present in many cells are dense clusters of small vesicles embedded in a deeply staining matrix noted in stage III (fig. 15). In some cells, these bodies appear as a single, enlarged, spherical vesicle with a deeply staining cap on one side or a thin sheath stretched around its periphery (fig. 15). Occasionally the cap is elongated so that the whole structure has the appearance of a tennis racquet (fig. 14). The larger of these optically clear vesicles are readily demonstrated, by means of a polarizing microscope, to be starch grains. The smaller vesicles could not be so tested but it is highly probable that they are starch grains.

Mitochondrial grouping.—The previously mentioned (stage III) solitary grouping of mitochondria³ is now readily discerned (fig. 17, 18, 20, 22, 24). The whole structure appears as a cluster of attenuated elements distinctly different in form from either the granular mitochondria or the plastid primordia present in the cells. Each element, of which there are a large but varying number in the cluster, is composed of a darkly staining, swollen head portion which tapers rapidly into an elongated, filamentous tail. The end of the tail is beyond the visibility of the microscope. The elements are usually so grouped that the tail portions arise in a lightly staining, optically homogeneous area (fig. 17, 18, 20, 24). The swollen head portions thus extend in all directions. Only rarely do any of the head portions appear vesiculated. Often the filamentous portions, while extending outward, are twisted and curved (fig. 17, 18). The elements retain the stain intensely after fixation in modified Erliki's-pyridine (fig. 17, 18, 20); it is on the basis of their preservation in this solution that they are here regarded as mitochondrial in nature. They stain only lightly after fixation in Bensley's mixture, as do the other cytoplasmic ele-

³ The labeling of these bodies as mitochondria is purely arbitrary. The term as here used merely indicates that they are preserved by those fluids which fix mitochondria and are dissolved by the fixatives which destroy mitochondria.

Fig. 8-16.—Fig. 8-9. *Triticum*. Shoot 11 mm. Chromium sulfate-formalin.—Fig. 8. Enlarged distal and basal vacuoles contain irregularly precipitated clumps of vacuolar material.—Fig. 9. Cell from the same section as cells in figure 8. The distal vacuoles contain the homogeneous precipitate. Note the presence of the empty basal vacuole.—Fig. 10. *Triticum*. Shoot 30 mm. Chromium sulfate-formalin. Large vacuoles, most of which are filled with the homogeneous precipitate, extend throughout the cells. Note the empty basal vacuoles. Small empty vacuoles are present in the homogeneous vacuolar precipitate in the cell on the right.—Fig. 11. *Triticum*. Shoot 12 mm. Modified Erliki's-pyridine. The mitochondrial grouping is evident in the left cell. The homogeneous area in which it is contained is not readily delineated. Note several plastids in addition to numerous plastid primordia and granular mitochondria.—Fig. 12-13. *Secale*. Shoot 29 mm. Chromium sulfate-formalin. Large extended vacuoles contain irregularly precipitated clumps of vacuolar material. Compare with figure 10. Note large vacuolar granules.—Fig. 14-15. *Secale*. Shoot 28 mm. Modified Erliki's-pyridine. Various shaped plastids containing starch grains are present. Note granular mitochondria.—Fig. 16. *Triticum*. Shoot 20 mm. Bensley's. Large vacuoles containing the homogeneous precipitate and the empty basal vacuole are present. Note lightly staining plastid primordia and plastids. All figures $\times 1,550$.

ments in the cell, and the head portions are not so swollen as they are after fixation in modified Erliki's-pyridine (fig. 24). In cells killed in modified Erliki's-formalin, the structure is only vaguely discernible, staining slightly more deeply than its cytoplasmic

Fig. 17. *Secale*. Shoot 25 mm. Modified Erliki's-pyridine. Note plastid primordia, granular mitochondria and several small mitochondrial filaments. $\times 2,300$.

surroundings (fig. 22). It is not discernible after chromic sulfate-formalin fixation. The structure is not present in the granular cytoplasm; it is confined to a lightly staining homogeneous region the fixation image of which appears very similar to the previously described homogeneous material precipitated within the vacuole (fig. 17, 18, 24). This region appears, in many cases, to have been pulled away from the surrounding granular cytoplasm so that a thin,

peripheral, clear zone is discerned after fixation in both modified Erliki's-pyridine and modified Erliki's-formalin (fig. 17, 18, 22). In some cells fixed in the latter solution the central portion of this region stains more deeply (fig. 22). When Bensley's fixative is used, this region is so fixed that it is in intimate contact with the granular cytoplasm. When thus fixed it is extremely difficult to delineate the region accurately (fig. 24). This is also true of the above mentioned precipitated vacuolar material (fig. 16.) Often the homogeneous region occupies little more area than the mitochondrial grouping contained within it (fig. 17). In other cases, the region is more expanded, extending beyond the grouping and appearing not unlike the previously described extended vacuole containing the homogeneous precipitate (fig. 24). It is difficult at times to determine whether or not the elements of the grouping extend beyond the homogeneous region into the surrounding cytoplasm. Usually, however, they appear to be confined within the region, although some of the head portions often extend to its very limits. In cells in which the grouping is more expanded, the greater number of elements extend necessarily toward the basal and distal ends of the cell because of the elongated cell shape (fig. 24). While in many cells the grouping is present just distad to the nucleus, its position varies from basal to distal. It appears only occasionally, however, in the region basal to the nucleus (fig. 22). The specimens varied in the number of cells in which the grouping could be demonstrated: in some, the greater number of cells contain the structure; in other, it could be delineated only occasionally. Since the fixation image of the homogeneous area housing the grouping appears very similar to the vacuolar homogeneous precipitate and since it is a definite zone set off from the granular cytoplasm, often being pulled away from it in fixation, it would appear that this region is vacuolar in nature. If this conclusion is correct, such a structure would indeed be unique in that it contains elements of mitochondrial nature which, moreover, assume a definite orientation, a condition in itself unique. It should be emphasized again, however, that future investigation may make it more convenient to consider this structure a highly specialized portion of the cytoplasm rather than a discrete vacuole.

As is evident from the accompanying figures, the cells of all specimens have not attained equal length at this period of germination. In some, the cells have reached a maximum length, and the lateral separa-

tion is pronounced; in others, the cells are apparently lengthening. There is a clear correlation between the length of the cells and their position in the epithelium: the cells are longer in the anterior region and shorter in the posterior. The gradation in length is regular. This difference in cell length persists until the end of germination. It is also in the anterior region that the cells attain greatest lateral separation, at the same time becoming highly irregular in shape, particularly in the final stages of germination. In some specimens this occurs to a lesser degree in the cells in the posterior region. In the majority of specimens, little or no separation or distortion characterizes the cells in the central region of the layer.

STAGE V.—*Vacuoles*.—As germination continues, there is little change in the epithelial cells over an extended period, and it is not until the endosperm is almost depleted that more pronounced alterations occur. Thus, even when the shoots have reached a length of 7 or 8 cm., the condition of the cells in many specimens varies little from that in the last described stage. The usually empty, basal vacuole is present in the majority of cells, although even at this stage it is of infrequent occurrence in some specimens. Its presence was also reported by Guilliermond (1908) as characteristic of the later stages of germination. In some of these vacuoles an irregular precipitate occurs. The majority of cells still show the extended areas of lightly staining, homogeneous vacuolar precipitate, which, as previously noted, is often contiguous with the empty, basal vacuole or, when the latter is not present, frequently extends into the basal region of the cell (fig. 25). When the nucleus occurs in the distal region of the cell, the homogeneous area often extends from the proximal end of the nucleus to the empty basal vacuole. In a few cases, when the empty vacuole is not completely basal, the homogeneous area borders on both its distal and proximal sides. In some specimens the homogeneous material appears to have been pulled away from the vacuolar membrane, probably as the result of fixation (fig. 23, 25).

In a number of cells in the anterior region of the epithelial layer of many specimens, the vacuoles do not contain the characteristic homogeneous precipitate but instead contain irregular clumps of precipitated material. In a few specimens this condition appears in cells dispersed throughout the whole layer. In other grains, particularly toward the end of this stage, this condition is characteristic of the majority of cells (fig. 27), and only an occasional cell

Fig. 18-25.—Fig. 18-19. *Secale*. Shoot 25 mm. Modified Erliki's-pyridine. Cells from the same specimen as the cells illustrated in figure 17.—Fig. 18. Note the varying form of the mitochondrial grouping when compared with figure 17.—Fig. 19. The mitochondrial grouping is not present. Note the variously shaped plastids and the granular mitochondria.—Fig. 20. *Triticum*. Shoot 25 mm. Modified Erliki's-pyridine. The cytoplasmic inclusions are similar to those illustrated in figures 17-18, although the homogeneous area containing the mitochondrial grouping is not as sharply delineated.—Fig. 24. *Triticum*. Shoot 20 mm. Bensley's. The lightly staining mitochondrial grouping is evident. The cell is from the same specimen as the cell illustrated in figure 16.—Fig. 21. *Triticum*. Shoot 29 mm. Bensley's. Note the small empty vacuoles contained in the homogeneous vacuolar precipitate.—Fig. 22. *Secale*. Shoot 25 mm. Modified Erliki's-formalin. Two cells contain the mitochondrial grouping. Note the deeply staining center of the grouping. Lightly staining plastid primordia are present in the middle cell.—Fig. 23 and 25. *Secale*. Shoot 60 mm. Modified Erliki's-formalin. Extending throughout the cell are large vacuoles containing the homogeneous precipitate. Note the large, deeply staining vacuolar granule embedded in the homogeneous material. All figures $\times 1,550$.

displays the homogeneous precipitate. Since the vacuoles are usually empty at the end of germination this condition must indicate a gradual depletion of the vacuolar material that is precipitated in fixation.

There is no marked change in either the plastid or mitochondrial complex at this stage. In many cells the plastids contain enlarged starch grains; in others the typical plastid primordia are retained. The number of granular mitochondria has not decreased when this stage of germination is reached. There is little change in the peculiar mitochondrial grouping, either in form or position (fig. 26).

STAGE VI.—Vacuoles.—At the end of germination, as the endosperm becomes emptied, the shoots attain a length of from 12 to 15 cm. At this stage the cells are highly vacuolate, the vacuoles appearing empty or at most containing a few irregular clumps of precipitated material (fig. 31). In many cells only a thin peripheral layer of cytoplasm is present so that large, empty vacuoles occur on either side of the nucleus, a condition also observed by Guilliermond (1908). In cells which are evidently beginning to disintegrate, the nucleus stains irregularly and in some specimens becomes rounded, while in others it assumes an irregular form (fig. 29, 30). In other specimens the contents of some of the cells appear to have dissolved so that little is left except the cell wall.

Plastids and mitochondria.—The plastid and mitochondrial elements evidently persist until the cells begin to disintegrate. A number of the large plastid primordia are still present in many cells (fig. 29, 30). A definite plastid with contained starch grains is discernible in rare instances. The granular mitochondria are still evident (fig. 29, 30). Horning and Petrie (1927) reported the disappearance of the migratory mitochondria as germination draws to a close, a condition they identified indirectly with cessation of secretory activity. It is to be noted, however, that on the completion of the germination process the epithelial cells begin to disintegrate, and it is quite possible that to this condition is due the disappearance of cytoplasmic inclusions.

Mitochondrial grouping.—The mitochondrial grouping can still be demonstrated in some cells at this stage. It is now greatly contracted, appearing as a darkly staining rosette. From the usually deeply staining, undifferentiated center, the head portions project in all directions (fig. 29, 30). The elongated tails have evidently contracted to draw the head portions together. The homogeneous area in which the grouping is contained in earlier stages is here not

discernible. While the exact position of the dense grouping in relation to the vacuole is at times difficult to discern, there is evidence to indicate that it is present within the vacuole. Usually it appears to be confined within an area devoid of cytoplasm which evidently is a vacuole. While a portion of the rosette may extend to the cytoplasm, the greater part appears free in the vacuole (fig. 29, 30). It is to be noted that in a specimen of comparable shoot length in which the epithelial cells are not so advanced as here described, the grouping in most cells appears as in earlier stages and is contained within the homogeneous area. In a few cells, however, the grouping, although still within the homogeneous area, assumes the contracted form characteristic of the final stage (fig. 28). In still other cells, while the greater number of elements are contracted to form a dense rosette, a few retain the elongated form and project a distance beyond the main grouping, but are still contained within the homogeneous area (fig. 32).

With endosperm depletion, the secreting and absorbing activity of the epithelial cells comes to an end. This cessation of function is accompanied by an obvious disintegration of the specialized structure which characterizes the cells. The cells themselves soon die and disintegrate.

Discussion.—While it is evident that the epithelial cells of the scutellum are gland cells, the changes occurring during activity and the presence of specific structures must be interpreted in terms of two functions, since the cells absorb the digested endosperm material as well as secrete enzymes.

Vacuoles.—Neither the structure nor the position of the vacuoles in the epithelial cells give positive evidence that they play a rôle either in secretion or absorption. The nature of the precipitated homogeneous material present within the vacuoles is as yet undetermined. It is highly probable that some of the soluble carbohydrates absorbed from the endosperm collect in the vacuoles, but such a substance would not be precipitated by the type of fixation here used. The fact that the material is precipitated by the mitochondrial fixatives indicates perhaps that it is of a protein nature. Such a supposition suggests several possibilities as to its origin. That it might be a fixation image of a fine dispersion of a colloiddally dispersed protein which remains within the vacuoles after the dissolution of the aleurone grains is extremely doubtful. Such a conclusion, moreover, would not be supported by the earlier observations of Guilliermond (1908). Another possibility is that the precipitated substances is actually an enzyme, pos-

Fig. 26-32.—Fig. 26. *Triticum*. Shoot 95 mm. Bensley's. The mitochondrial grouping contained within the homogeneously precipitated area is present.—Fig. 27. *Triticum*. Shoot 80 mm. Modified Erliki's-formalin. Large vacuoles extending throughout the cell contain irregularly precipitated clumps of vacuolar material. Note the vacuolar granules.—Fig. 28 and 32. *Triticum*. Shoot 110 mm. Modified Erliki's-pyridine. A solitary contracted mitochondrial grouping is contained within the homogeneous area. In figure 32 some of the elements of the contracted grouping are still extended, their form appearing very similar to that of earlier stages.—Fig. 29-30. *Triticum*. Shoot 150 mm. Modified Erliki's-pyridine. In two cells the mitochondrial grouping is greatly contracted and now no longer appears to be contained within the homogeneous area. The vacuoles are empty. Note plastid primordia and granular mitochondria.—Fig. 31. *Triticum*. Shoot 150 mm. Modified Erliki's-formalin. The greatly extended vacuoles contain only a few irregularly precipitated clumps of vacuolar material. Note vacuolar granules. All figures $\times 1,550$.

sibly a protein, produced by the epithelial cells and collected in the vacuoles before it is discharged, in some unknown manner, into the endosperm. As previously noted, this homogeneous material is concentrated particularly in the distal region of the cell and, as the endosperm approaches complete depletion, it tends to disappear.

The position of the empty, basal vacuole suggests that it functions in absorption. The soluble carbohydrate material absorbed from the endosperm by the epithelial cell may collect temporarily in this vacuole from which it is eventually carried away through the scutellar parenchyma to the growing plant.

Plastids and mitochondria.—Of the three types of inclusions preserved by the mitochondrial fixatives in the epithelial cells during germination, a definite function can be assigned to only one. The large, usually rod-shaped bodies are plastid primordia. These inclusions readily develop into plastids as optically clear vesicles which can be identified as starch grains form within them. In typical meristematic cells, two categories of mitochondria have been recognized, the one composed of plastid primordia, the other including the forms not developing into plastids. Satisfactory criteria for differentiating the two categories are still unavailable. In the epithelial cells, however, plastid primordia can be differentiated on the basis of size and shape from non-plastid-forming mitochondria. It is concluded that all of the large, usually rod-shaped inclusions are plastid primordia, since in addition to the fact that it is only from this type of inclusion that the plastids arise, there is the further evidence presented in some cells in which practically all of these bodies have developed into plastids (fig. 14, 19). The presence of such structures can be interpreted in terms of absorption only, for they function as a temporary storage place for starch which is later reabsorbed as germination draws to a close.

No definite function can be assigned to the numerous minute granular mitochondria present throughout germination. It is possible that they belong in the same category as the non-plastid-forming types of mitochondria found in meristematic cells and have arisen from such types as the development of the epithelial cells proceeds from undifferentiated meristematic tissue. The evidence at hand, other than their existence in large numbers, does not warrant an assumption that they here acquire a function connected with the specialized activity of the epithelial cells.

Mitochondrial grouping.—The grouping of the large mitochondrial elements in the epithelial cells is unique. The elements themselves are peculiar in that, when fixed, they always assume a form in which a definite head and tail can be differentiated. In addition, the elements are definitely oriented in a characteristic group. They are not present in the granular cytoplasm but are contained within a homogeneous region which the evidence at hand indicates to be a highly specialized type of vacuole. The structure as here described has been observed only in fixed cells,

so what has actually been seen is a fixation image of a cell inclusion that may have a somewhat different form in the living cell. However, since several types of fixative preserve the structure with little change in form, its fixation image may approximate very closely its structure in the living cell. As far as is known, such a structure has not been previously reported as occurring in any other type of cell. The evidence at present does not warrant the assigning of a particular function to this structure; but the fact that it occurs only in specialized glandular cells perhaps indicates that it is associated in some way with secretory activity. Such an assumption must be made with caution, however, for in the past, the mere presence of a particular body within a cell has led many investigators to assign a specific function to the body without the support of critical evidence.

It must be noted that there is some indication of the presence of the mitochondrial grouping in the sub-epithelial layers of the parenchyma cells of the scutellum as well as the other types of inclusion and the homogeneous vacuolar material. A cytological investigation of these cells is in progress.

SUMMARY

The epithelial cells of the scutellum of *Triticum sativum* and *Secale cereale* are organs of secretion and absorption. The internal changes occurring in the cells during the course of their activity and the presence of specific structures are considered in terms of these two functions.

As germination begins, small vacuoles form in the cells through the swelling and dissolution of aleurone grains present in the resting stage. As germination progresses, these vacuoles enlarge and coalesce. In the large vacuoles thus formed, there appears a vacuolar material which is precipitated in fixation as a lightly staining homogeneous mass. This material, possibly protein in nature, disappears at the end of germination, at which time the cells are completely vacuolate and devoid of vacuolar material.

Plastid primordia, separated on the basis of size and shape from non-plastid-forming mitochondria, are present in the epithelial cells during germination. These bodies readily develop into plastids as starch grains form within them.

Present also in the epithelial cells are two types of non-plastid-forming mitochondria. The first is represented by a profusion of minute granular bodies of unknown function occurring free in the cytoplasm. The second type of mitochondria, so designated because it is preserved by certain fixatives, does not occur freely dispersed; instead, these elements, each composed of a filament and enlarged terminal portion, are localized in a characteristic solitary group. The filamentous portions project in all directions from the center of the group and terminate in swollen heads. The structure is not present in the granular cytoplasm but is contained within a homogeneous region indistinguishable from the precipitated homogeneous vacuolar material. While this region may be a highly specialized portion of the cytoplasm, the

evidence at hand indicates that it is vacuolar in nature. Relationship between the structure and secretion is suggested.

THE RELATIONSHIP OF RANUNCULUS TO THE NORTH AMERICAN FLORAS¹

Lyman Benson

THE OBJECT of this paper is to present the broad outlines of the geographical distribution of *Ranunculus*, which have emerged as a result of monographing the group for North America north of Mexico (Benson, 1936, 1940, 1941-2) and as a result of collecting 11,000 plant specimens, including several hundred sheets of *Ranunculus*, in the field. Combined with an interpretation of the distribution of the genus is an attempt to classify the many vegetation-areas with which the genus is associated, and to point out the significance of *Ranunculus* in the definition of major floristic areas and in the determination of the possible origin and relationships of the North American complex of floras.

The distributional pattern of *Ranunculus* in North America is by no means obvious, since it is complicated by the fact that the genus includes at least three distinct phases or groups of species, as follows: (A) the widespread aquatic and palustrine types; (B) the relics of ancient floras; (C) the dominant phase of the genus.

A. THE WIDESPREAD AQUATIC AND PALUSTRINE TYPES.—Although some aquatic, palustrine, or sub-palustrine species and varieties are of restricted distribution and are characteristic of particular areas, most are widespread, and their ranges are not necessarily restricted by exactly the same set of factors which governs the occurrence of terrestrial species. The widespread species of *Ranunculus* are as fol-

lows: EURANUNCULUS. Sect. *CHRYSAN-
THE*. *R. Macounii*, *R. pensylvanicus*. Sect. *FLAM-
MULA*. *R. Flammula* vars. *ovalis* and *filiformis*.
Sect. *HECATONIA*. *R. sceleratus*, which may be
introduced, *R. sceleratus* var. *multifidus*, *R. Gmelinii*
var. *terrestris* (*R. Purshii*), *R. flabellaris* (*R. del-
phinifolius*). CYRTORHYNCHA. Sect. *HAL-
ODES*. *R. Cymbalaria* and its varieties. BATRA-
CHIUM. *R. aquatilis* var. *capillaceus*, *R. circinatus*.

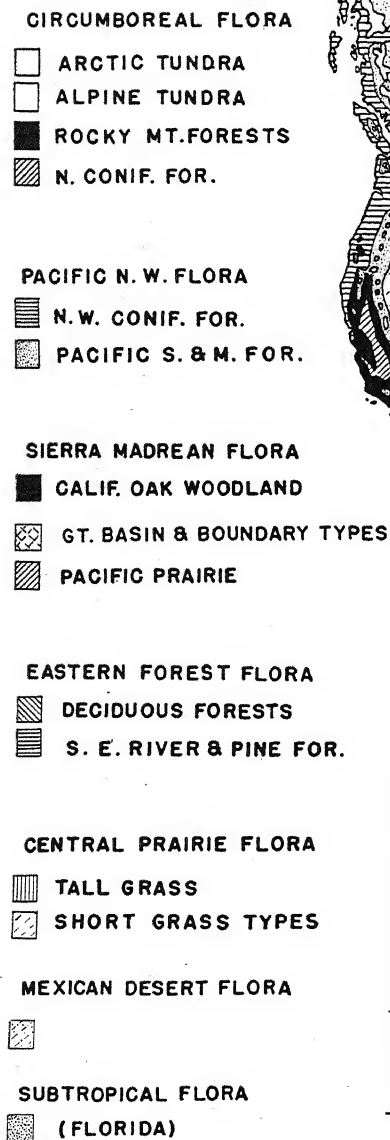

B. THE RELICS OF ANCIENT FLORAS.—Five of the seven native subgenera are small or monotypic and are represented by isolated species of disjunct distribution, as follows:

a. *Cyrtorhyncha*.—Eliminating the widespread palustrine types of the section *Halodes*, the subgenus is represented in North America by three monotypic sections, the species of which are discussed below: *Ranunculus ranunculinus* is an endemic of the frontal range of the Rocky Mountains in southeastern Wyoming and in Colorado. *R. Cool-
eyae* is known from coastal Alaska, from scattering mountain stations in coastal British Columbia and from a point at the southern end of the Olympic Mountains in Washington just southwest of the tip of the Kansan ice-sheet. *R. hystriculus* has a range in California almost coinciding with that of the Big Tree, *Sequoiadendron giganteum* or *Se-
quoia gigantea*, in the Sierra Nevada, and may share its antiquity. According to Asa Gray (1886, p. 365), *R. hystriculus* is approached in its dis-

¹ Received for publication February 18, 1942.

THE SECTION EPIROTES

tinctive fruit characters by "certain New Zealand and Aucklandian Ranunculi." If these Antipodal species are as nearly related as Gray indicated, the distribution of the group is of a remarkably disjunct type, and it is almost certainly ancient. Each of the three species is definitely on the down-grade, depleted of bio-types, without adaptability, merely hanging on in favorable localities wherein it must have been long established.

b. *Oxygraphis*.—The single American species, *R. kamchaticus*, occurs in boreal and alpine Asia and on the Seward Peninsula of Alaska. This species and *R. Chamissonis* (subgenus *Crymodes* below) may be additional examples of plants which once occurred along an intercontinental land-bridge and which persisted on the American side of Behring Strait during the Pleistocene glaciations (Nelson, 1887; Adams, 1905, p. 58). (Northern Alaska was not glaciated in Pleistocene time.)

c. *Crymodes*.—This subgenus consists of two groups of species, as follows: (1) boreal and alpine types, including *R. glacialis* (Greenland, Iceland, and Europe), *R. Chamissonis* (Siberia, and north-western Alaska), and *R. Shaftoanus* (Afghanistan); (2) western North American semi-desert types, including *R. Andersonii* and *R. juniperinus* (Southwestern Coniferous Woodland or juniper-pinyon type and Northern Desert or sagebrush type in the Great Basin).

d. *Pallasiantha*.—*R. Pallasii* may be restricted to non-glaciated areas, since it occurs in northern Alaska and in scattering areas along the Arctic Ocean and at one station on the Arctic Archipelago (Polunin, 1940). (Parts of the Arctic shore and nearly all of the Archipelago remained unglaciated in Pleistocene times.) This species, which is not aggressive, is without close relatives, and lacks variability, may be the last surviving type of a more plastic population practically exterminated by glaciers. However, herbarium specimens are not abundant enough to indicate the exact distribution of Arctic species, and it is difficult to match up the data on all the labels with glaciated and unglaciated areas.

e. *Coptidium*.—*R. lapponicus* encircles the earth in boreal regions and in sub-boreal forests, but its distribution is not wholly continuous.

Although the species of the five subgenera discussed above show a disjunct distribution, their occurrence is in accord with the following outline. The greatest development of the group as a whole is in boreal and northern alpine regions or sub-boreal or subalpine forests of Eurasia and North America, and the species-groups with the most nearly continuous distribution occur in these areas. One group (that cited by Gray) is represented in New Zealand, and others occur as scattered endemic relics in western North America. It is possible that the discontinu-

ously distributed, unaggressive small subgenera represent relics of specialized branches of an older phase of the genus than is represented by the now more abundant and variable and frequently aggressive sections of the subgenus *Euranunculus*. If this is true, however, it is to be noted that the flowers of some and the fruits of all the surviving species have considerably more highly specialized features than those found in *Euranunculus* (cf. Benson, 1940, pl. I, and the keys to the subgenera and sections). The surviving types must represent only a small selection from a once highly variable and very extensive series of species, differentiated long ago.

Two other groups of relic-species indicate relationship of North American floras to those of other continents.

a. *Pacific Coast*.—As mentioned by Abrams (1929), many California plants are clearly related to Old World groups, and as shown by Fernald (1929) in the same series of papers, many of the species of Pacific North America are identical with or related to those of Western Europe, while the eastern North American Flora has elements in common with the eastern Asiatic flora. In the California Oak Woodland and in disjunct areas in Western Oregon and the Palouse Region in Washington and Idaho, *Ranunculus hebecarpus* is a common and characteristic species, and it is the only American representative of the section *Echinella* of the subgenus *Euranunculus*, a group strongly centering in Western and Central Europe and the Mediterranean Region. Furthermore, the Pacific Coast endemic, *R. Lobbii* (subgenus *Batrachium*), has no close American relatives, and, according to W. B. Drew (1936, p. 8), it is most closely related to the European species, *R. tripartitus*. As may be expected with an ancient relic-species, its distribution is discontinuous, since it occurs on Vancouver Island in British Columbia, at Corvallis in Oregon, and in the San Francisco Bay Region in California.

b. *Atlantic Coastal Plain*.—*Ranunculus Flammula*, a well-known European species, occurs in North America in southeastern Newfoundland, where (Fernald, 1917, p. 135) "... it is associated with many other typical western European species unknown elsewhere in North America. . ." Another European *Ranunculus*, *R. hederaceus*, occurs in the same area as well as on the floristically related (Fernald, 1911) Atlantic Coastal Plain in Chester County, Pennsylvania, and about Chesapeake Bay as well as (according to report) in South Carolina. *R. Ficaria* grows also in a few localities on the Coastal Plain, but it has been considered as introduced.

C. THE DOMINANT PHASE OF THE GENUS.—With the widespread aquatic and palustrine types and the ancient relic phase of the genus disposed of, the re-

Plate I.—Fig. 1-2. The North American Floras.—Fig. 1. Map showing the distribution of the North American Floras. Some subdivisions are combined as indicated in the legend.—Fig. 2. Bar diagram showing the relative numbers of species in the section *Epirotes* and other sections in the floras in which the genus is well represented. The section *Epirotes* dominates three subdivisions of the circumboreal flora, i.e., the Arctic Tundra, the Alpine Tundra, and the Rocky Mountain Forests, and elsewhere it is represented by only a few species all of which are aberrant.

maining species and varieties, which are practically all in the subgenus *Euranunculus* and which constitute the bulk of the species, may be segregated with ease into clear-cut geographical groups. These groups correspond to the following North American regional floras: the Circumboreal Flora, the Pacific Northwestern Flora, the Sierra Madrean Flora, and the Eastern Forest Flora. In addition to these four floras, three others occur in North America north of Mexico, but they will not be discussed in this paper, since *Ranunculus* is not represented in them or is represented by only a few terrestrial types. They are as follows: the Central Prairie Flora (tall grass and various short grass types), the Mexican Desert Flora (creosote-bush type), and the Subtropical Flora (mangrove; everglades).

1. *The circumboreal flora.*—For reasons to be given in the succeeding paragraphs, the following vegetation-types are included in the Circumboreal Flora: the Arctic Tundra, the Alpine Tundra, the Rocky Mountain Forests (subalpine and montane taken together), and the Northern Coniferous Forest.

The distinctness of the boreal flora is well-known, and, as has been pointed out by J. D. Hooker (1862) and others, it has had a nomadic existence, having followed the movements of glaciers, appearing always along their margins. In view of the northward and southward migrations of ice-sheets through the ages, it is not surprising that it is possible to trace the relationship of the *Ranunculi* and other plants growing in polar regions to those in the ecologically similar alpine type to the southward. However, it is surprising that in the case of *Ranunculus* relationship can be traced to the species occurring in the Rocky Mountain subalpine and montane forests but not to those in forests of apparently similar ecological type occurring elsewhere on the continent.

Although the species of *Ranunculus* occurring in the North American Arctic Tundra, Alpine Tundra, and Rocky Mountain subalpine and montane forests are for the most part mutually exclusive, their close relationship to one another is obvious, since they are dominated by the section *Epirotetes* of the subgenus *Euranunculus* and since the species of this section occurring elsewhere are few and aberrant (cf. solid areas in figure 2). In the region as a whole there are forty significant native species and varieties (excluding, as in all the rest of this paper below, very weakly represented plants and the types discussed under A and B above). Twenty-nine of these are in the section *Epirotetes*, and these include all but six of the thirty endemics. In the other floras, the section is represented by only three small, aberrant groups, as follows: *R. glaberrimus* and its varieties (Great Basin and northern Great Plains), *R. rhomboideus* (Central Prairie Flora), *R. abortivus*, *R. micranthus*, *R. allegheniensis*, *R. Harveyi*, and their varieties (largely in the Eastern Forest Flora).

The predominance of the section *Epirotetes* in the arctic-alpine-cordilleran area as a whole is also characteristic of each of the principal subdivisions

(solid areas in figure 2), except, as will be shown in the next paragraph, the Northern Coniferous Forest. In the Arctic Tundra eight of the ten species and all four endemics are in the section which includes, in the Alpine Tundra, twelve of the thirteen species and varieties and all eleven endemics, and in the Rocky Mountain Forests eleven of the nineteen species and varieties and nine of the fourteen endemics.

The failure of the section *Epirotetes* to become established in the Northern Coniferous Forest (spruce-fir type) in Eastern Canada and along the border of the eastern United States seems anomalous for the following reasons: the area seems to be ecologically ideal; the species of the section are dominant both in the arctic regions just to the north and in the Rocky Mountain Forests just to the southwest; many other species and species-groups are related to those in the Rocky Mountain Forests. An explanation of this failure of *Ranunculus* to reflect the relationship of the Northern Coniferous Forest to sub-boreal and subalpine forests throughout the Northern Hemisphere and particularly to the sub-alpine and montane forests in the Rocky Mountains may be attributed to the lack of aggressiveness of the section *Epirotetes*. The area occupied by the Northern spruce-fir forest is approximately that denuded by glaciers in the Pleistocene period, and, were the members of the section *Epirotetes* developing new types and actively spreading, they should be expected to have filled in this area immediately or at least to have invaded the borders. This sluggishness of the typical members of the section in the East is matched by similar inactivity in the West, for only one Alpine Tundra or Rocky Mountain Forest species (the alpine *R. Eschscholtzii*) has penetrated northward along the glaciated mountains, and only one of the boreal species (*R. pedatifidus*, which is really sub-boreal) is represented in the Western mountains by more than scattered relics, probably of pre-glacial times (and there are very few of these²). Of the twenty-two species of *Ranunculus* actually occurring in the Northern Coniferous Forest,³ nine are widespread aquatic and palustrine types eliminated from consideration, and the rest are obvious derivatives of groups in adjacent areas other than the Rocky Mountain Forests. These are confined to ranges adjoining their parents. Since the spruce-fir forest of the north has been filled in not by the expected derivatives of the section *Epirotetes* but by aggressive widespread types and, along its borders, by Alaskan and Eastern Forest neighbors, it is

² *R. hyperboreus* (sect. *Hecatonia*) has a relic-colony on Old Hollowtop near Pony, Montana, and *R. pygmaeus* (section *Epirotetes*) occurs in the Canadian Rockies and on a few peaks as far south as Colorado. A collection from Capitol Peak (Penland, 1512, cf. Penland, 1941, p. 13) may be *R. nivalis*.

³ The area is poor in endemic *Ranunculi*, a fact in harmony with the findings of Raup (1941), who in seven seasons in the remote Athabasca-Great Slave Lake region found only two new species, except in sand-dunes, a habitat-type often rich in endemic relics in this area (Adams, 1902, p. 310) but uninhabitable for *Ranunculus*.

necessary to depend largely upon other floristic elements to determine its relationship to the Circumboreal Flora.

Having correlated the *Ranunculus* floras of the boreal, alpine, and cordilleran forest regions with one another, and having advanced a possible explanation for lack of correlation of these *Ranunculi* with those of the floristically related Northern Coniferous Forest, it is well to examine samples of other elements in the flora to determine whether their distributional patterns are in agreement.

Although (as is true of *Ranunculus*) the pteridophytes occupying the other major floral areas are largely endemic⁴, those growing in the arctic-alpine areas and the forests of the northern part of the continent are chiefly widely-distributed Eurasian-North American species, some of which extend southward into the other floral regions. These widespread boreal northern-forest, and subalpine-forest species are almost the only ones occurring in the Rocky Mountain Forests, where there are not more than half a dozen characteristic or endemic species. It is to be noted that these same species flourish in the glaciated areas defaulted by the section *Epirotes*, thus strengthening the contention that, in large part, the Northern Coniferous Forest is a portion of the Circumboreal Flora.

The circumboreal origin of the bulk of the Rocky Mountain Forest flora receives a negative sort of support from the shortage of gymnosperm species, which possibly may be correlated with their almost complete absence, in the Arctic Tundra extending around the world. In the Rocky Mountain Forests there are only eight species or varieties which are endemic or essentially⁵ so, and (excluding two Mexican species growing near the Boundary) only fourteen altogether. A more positive support is gathered from two junipers (*Juniperus communis* and *J. Sabina*), which occur near timber-line around the Northern Hemisphere and which are well-developed in the Rocky Mountain Forests but not in either the Pacific Northwestern Flora or the Eastern Forest Flora.

2. *The Pacific Northwestern Flora*.—The following subdivisions are included in the Pacific Northwestern Flora: the Northwestern Coniferous

⁴ The Pacific Northwestern Flora includes about thirty-five endemic pteridophytes, the Sierra Madrean Flora, twenty or more, north of the boundary, and the Eastern Forest Flora, fifty or more.

⁵ *Pinus flexilis*, *P. aristata*, *P. ponderosa* vars. *scopulorum* and *arizonica*, *Picea pungens*, *Abies concolor* (excluding var. *Lowiana* of the Pacific Coast), *A. arizonica*, and *Juniperus scopulorum*. In the Pacific Northwestern Flora there are a total of thirty-three gymnosperms of which twenty-five are endemic (the eight non-endemic species being shared with the Rocky Mountain Forests). In the Sierra Madrean Flora there are twenty-four species north of the Border, all endemics. In the Eastern Forest Flora there are twenty-two endemic species and along the margins two widespread northern junipers. A number of Pacific Northwestern species reach the Rocky Mountain System in Montana and Idaho, but this area belongs floristically with the Pacific Northwest.

Forest⁶; the Pacific Subalpine and Montane Forests. The Palouse Prairie is included with some hesitation because of its affinity in some degree with other grasslands and because, at least in so far as *Ranunculus* is concerned, it is merely a meeting ground for species of adjoining areas. On the map (fig. 1) it is not differentiated from the Great Basin types of the Sierra Madrean Flora to which it is also related.

As pointed out by Chaney (1925, 1938), the red-wood-forest occurred in the Miocene Epoch through not only the northern part of California but through the Pacific Northwest including the Columbia Basin, as well. With the subsequent uplift of the Cascade-Sierra Nevada Axis in late Miocene and early Pliocene, the rainfall and the temperature minimum in the Columbia Basin were reduced considerably, and mountain areas with new conditions were developed from Washington to California. It is possible that the present subalpine and montane members of the several species-complexes in *Ranunculus* are modified descendants of wider-spread populations once occurring on the forested Miocene plains. If this is the case, the species occurring today in the relatively little-modified coastal forest-belt and in the related area north and east of the Columbia Basin may be the prototypes of the species-complexes.

Four complex species or species-groups of *Ranunculus* are represented, each largely by a single type, in the relatively ancient and unmodified Northwestern Coniferous Forest. Each of these species (*R. occidentalis*, *R. Bongardii*, *R. orthorhynchus*, and *R. alismaefolius*) is replaced by varieties or closely-related species in the Cascade-Sierra Nevada Axis and the mountains in and about the northern Great Basin,⁷ as well as in southern Alaska, and in north-coastal California. Diffusion of the groups northward into the glaciated regions and southeastward into the Rocky Mountain System will be discussed directly below, but invasion southward into the California Oak Woodland will be taken up under that ecological type (cf. Sierra Madrean Flora below).

Reoccupation of the glaciated areas from Puget Sound northward to Alaska has been accomplished by the first three species-complexes listed above, all of which are in the section *Chrysanthae* of the subgenus *Euranunculus*, a group in which nearly all of the species are polymorphic, rich in biotypes, difficult of classification, and remarkably adaptable ecologically. The recent spread of the weedy European species, *R. acris*, *R. repens*, and *R. bulbosus* and their biotypes, into various parts of the

⁶ Lowlands of the Pacific Slope from Alaska to the red-wood-belt of northwestern California; inland north of the Cascade Mountains through British Columbia to the western side of Glacier National Park, Montana, and southward to parts of Idaho, where it reaches an elevation of 3,500 feet.

⁷ It is to be noted that in some cases these varieties have apparently followed some of the large rivers, which cut through the mountain-axis down to the coastal region, e.g. *R. Bongardii* var. *tenellus* along the Fraser, Columbia, and Klamath rivers and *R. orthorhynchus* var. *platyphylus* along the Klamath and Pitt-Sacramento rivers.

world, including North America, is illustrative of the aggressiveness of some species of the section *Chrysanthē*. The plastic *R. occidentalis-californicus-canus* complex is the Pacific Coast counterpart of these Old World species. The members of this species-complex occur in all parts of the Pacific Coast, and types ranging from subaquatic to distinctly terrestrial occupy such ecologically different areas as the cold Yukon Valley, the moderate and moist Northwestern Coniferous Forest, the warm and seasonally dry broad-leaf sclerophyll areas, and the hot and dry Pacific Prairie in the Great Valley of California. The spread of this group and of the *R. orthorhynchus* group and *R. Bongardii* northward into the glaciated areas in Washington, British Columbia, and southern Alaska and perhaps even beyond them into the Yukon Valley and the Aleutian Islands since the Wisconsin glaciation is in keeping with the characters of the section *Chrysanthē*. In marked contrast to the aggressive movement and rapid modification of this section is the lack of ability of the section *Epirotes* established in the arctic, alpine, and cordilleran areas to reoccupy the intervening glaciated areas (as discussed above) and the Pacific Subalpine and Montane Forests or the Northwestern coniferous forest.

Some of the groups mentioned above have spread southeastward into the Rocky Mountain System, where each is represented by satellites of the main bulk of the complex. Examples are as follows: *R. occidentalis* var. *montanensis* in southwestern Montana and adjacent Idaho and Wyoming and its possible derivative, *R. acriformis*, on the high plains of Wyoming and adjacent Colorado; *R. Bongardii* var. *tenellus* in the Bighorn Mountains in Wyoming and var. *Earlei*, an endemic in southern Colorado; *R. orthorhynchus* var. *platyphyllus* along the eastern side of the Great Basin as far south as the Wasatch and Uintah Mountains in Utah⁸; *R. alismaefolius* var. *montanus* in Southern Wyoming, Utah, and Colorado and *R. Collomae*, an endemic in southeastern Utah and adjacent Coconino County, Arizona.

3. *The Sierra Madrean Flora*.—According to Axelrod (1940, pp. 483–4), (1) the California Oak Woodland, (2) the California Chaparral, (3) the Southwestern Coniferous Woodland (juniper-pinyon type), (4) the Northern Desert (sagebrush type), and (5) the Southwestern Oak Woodland and Chaparral are derivatives of a Mexican woodland prototype, the Sierra Madrean Element, which migrated northward in the Oligocene Epoch and early Miocene and Middle Miocene times into the area now occupied by much of California and the Great Basin. With the uplift of the Sierra Nevada late in Miocene and early in Pliocene and the consequent

development of a continental climate east of the new mountain ranges, such characteristic California Oak Woodland species as the Digger pine (*Pinus Sabiniana*) disappeared from western Nevada. Subsequent development in California has produced a vegetation almost wholly distinct in species from the derivatives of the same prototype in the Great Basin,—that is, the Northern Desert and the Southwestern Coniferous Woodland. A sixth vegetation-type, the Pacific Grassland of the Great Valley of California is of obscure origin, and the original nature of the flora is not certain, although there is some evidence that it was a bunch-grass type. Nevertheless it is possible that in the main the Pacific Prairie should be classified floristically with the Sierra Madrean Flora. Only the California Oak Woodland and the Pacific prairie have significant *Ranunculus* populations of the dominant phase of the genus.

The California Oak Woodland supports a dense growth of annual grasses and herbaceous plants during the moist winter and spring growing season. Among the herbaceous perennials are *Ranunculi* of the section *Chrysanthē* and chiefly of the *R. occidentalis* complex. In keeping with the rest of the flora, all of the terrestrial *Ranunculi* are endemic to the woodland, or to it and part of an adjacent area. As may be expected in a relatively dry country, the number of species of *Ranunculus* is not as great as for the moist Northwestern Coniferous Forest, and the species present may be migrant derivatives of relatives in that area. It is to be noted that related *Ranunculi* are lacking in the other derivative vegetation-types of the Sierra Madrean Element, including the nearest modern equivalent, the Southwestern Oak Woodland and Chaparral of Arizona, New Mexico, and northern Mexico. Possibly this is due to the greater dryness of the present climate in these areas, but in any case a semi-xerophytic woodland of the probable original type is not a suitable place to look for much of the basic *Ranunculus* stock. It is more likely that the genus has spread into the warm and vernal moist California Oak Woodland chiefly from the adjacent Northwestern Coniferous Forest and that it has been unable to occupy the sagebrush, juniper-pinyon, and Southwestern Oak Woodland and Chaparral types, where winter rain stops abruptly at about the time when vernal temperatures finally rise high enough to favor growth.

A few species (of the *Ranunculus occidentalis* complex in the main) occur in the Pacific Prairie in the Great Valley of California. In all probability they are merely derivatives of relatives in the California Oak Woodland, which surrounds the Pacific Prairie.

4. *The Eastern Forest Flora*.—The Eastern Forest Flora includes the following subdivisions: the Deciduous Forests, the Southeastern River Bottom Forest, and the Southeastern Pine Forest. The best development of *Ranunculus* is in the Deciduous Forests.

⁸ Since the closely-related *R. macranthus* occurs in northern Arizona and southward to Mexico and Texas and since the *R. orthorhynchus-septentrionalis* complex is well-developed in Mexico, the direction of migration may have been northward perhaps in company with the Sierra Madrean Element in Oligocene and Miocene time. (Cf. the Sierra Madrean Flora. Cf. also discussion under Eastern Forest Flora).

The Eastern Forest Flora is characterized by several endemic species groups. The relationship of these compact groups to other types occurring in diverse directions is apparent, and the high percentage of endemic species indicates the antiquity of the present groups of *Ranunculi* in the Eastern Forests. The probable separate invasions of the prototypes of various complexes must have occurred long ago. The groups are as follows:

R. septentrionalis, *R. hispidus*, *R. carolinianus*, *R. fascicularis*, and their varieties, which are members of the group of species in the section *Chrysanth* characterized by long, straight achene-beaks. The species of this group are connected with their Pacific Northwestern relatives, the *R. orthorhynchus* group, by a chain of mutual relatives occurring across the southern part of the continent. *R. fascicularis* is related through its Texan variety *cuneiformis* to *R. macranthus*, which occurs in Mexico and Arizona as well as in Texas and which is barely distinguishable from some of the *R. orthorhynchus* group in the mountains of the Great Basin and on the Pacific Coast (cf. discussion under the Pacific Northwestern Flora above). *R. macranthus* has other relatives in Mexico, and the origin of the entire group of species now extending across the southern part of the continent may have been either on the Pacific Coast or in Mexico or possibly in the East (cf. footnote 8).

R. recurvatus (sect. *Chrysanth*) is related to and perhaps derived from *R. Bongardii* and its varieties, a group restricted to the Pacific Region and lacking such specialized features as the thickened, bulbous stem-base and the nectary-scale of the pocket-type (found in only *R. recurvatus* as far as the section *Chrysanth* is concerned (Benson, 1940).

R. abortivus, *R. micranthus*, *R. allegheniensis*, and *R. Harveyi* are an aberrant group in the section *Epirotes*, and they are the only plants of the section occurring in the forests of the East and Middle West. Since *R. abortivus* ranges from Alaska to British Columbia and into the Rocky Mountains as far south as Colorado as well as through the East and Middle West, it may be the prototype of the group. *R. arizonicus*, confined to Arizona and New Mexico, has been shown (Benson, 1940, p. 801) to be a connecting link between this group of species and *R. cardiophyllus*, which in turn shows relationship to still more orthodox species of the section. It is likely, therefore, that the four Eastern and Middle Western species are an offshoot in the section *Epirotes* derived from the Rocky Mountain Forest sub-center for the section.

R. ambigens is related to *R. Flammula*, a European species occurring as a relic in southeastern Newfoundland (discussed under part B above).

R. pusillus, *R. laxicaulis* (*R. oblongifolius* of authors), and their varieties. Any statement concerning the relationships of this group is deferred pending study of *Ranunculi* in other parts of the world.

Occurrence of *Ranunculus pusillus* in the northern California foothills might have been attributed

to casual introduction from the Southeast, had not Miss Carter's studies (Benson & Carter, 1939) shown conclusively that certain anomalous forms in the Sierra Nevada foothills are a distinct, related, endemic species, *R. alveolatus* Carter. This information strengthens the view that *R. pusillus* may be native and possibly relict in California. *R. alveolatus* may be another relic-type associated with it.

SUMMARY

The distribution of *Ranunculus* in North America north of Mexico is complicated by the existence within the genus of three phases, as follows: (A) widespread aquatic and palustrine types, which are not restricted in habitat by the same factors which limit terrestrial species; (B) relics of ancient floras; (C) the dominant phase of the genus, the species of which are largely in the subgenus *Euranunculus* and are nearly all terrestrial.

The relics of ancient floras include practically all the members of five of the seven native subgenera, and they may represent a phase of the genus with many highly differentiated types probably once well distributed through boreal regions and extending southward possibly to New Zealand and certainly throughout western North America. Other relics indicate relationship of the Pacific Coast Flora to that of Western Europe, and of the flora of Newfoundland and the Atlantic Coastal Plain to the Western European flora.

The species of the dominant phase of the genus may be segregated readily into geographic groups with distinct affinities to the following regional North American floras: the Circumboreal Flora, the Pacific Northwestern Flora, the Sierra Madrean Flora, and the Eastern Forest Flora. The genus is poorly represented or does not occur at all in the other floras, which are as follows: the Central Prairie Flora, the Mexican Desert Flora, and the Subtropical Flora.

The Circumboreal Flora includes the Arctic Tundra, the Alpine Tundra, and the Rocky Mountain Forests, which are bound together by the section *Epirotes*, which dominates all of them and which, in its typical form, is restricted to them. Absence of *Epirotes* in the Northern Coniferous Forest is explained by the lack of aggressiveness of the section or its apparent inability to fill in the areas denuded by glaciers in the Pleistocene Epoch.

The species-complexes of the Pacific Northwestern flora may have arisen along with differentiation of climates resulting from uplift of the Cascade-Sierra Nevada Axis in late Miocene and early Pliocene. The species occurring today in the relatively little-modified Northwestern Coniferous Forest may be the prototypes of the complexes, and apparently the derivative-members have migrated rapidly in all directions from the Pacific Northwestern center.

The Sierra Madrean Flora occupies most of California and the Great Basin and the lower mountains of Arizona, New Mexico, trans-Pecos Texas, and

northwestern Mexico. The vegetation types differentiated since uplift of the Sierra Nevada are mostly poor in *Ranunculi*. However, the Oak Woodland and part of the Pacific Prairie in California have been invaded from the Northwestern Coniferous Forest. The warm, rainy winters have made invasion possible in this area, but it has not been possible in the other Sierra Madrean areas where winter rains are light and are over before the weather is warm enough for growth.

The Eastern Forest Flora is characterized by compact endemic groups of species with relationships to groups occurring in several directions. The high percentage of endemism indicates the antiquity of the probable separate invasions of the prototypes of these groups.

THE ESTIMATION, ISOLATION, AND IDENTIFICATION OF AUXINS IN PLANT MATERIALS¹

A. J. Haagen-Smit, W. D. Leech, and W. R. Bergren

INVESTIGATIONS UPON the use of different types of extraction methods under varying conditions have indicated that the substances called auxins, which give a negative curvature of the *Avena* coleoptile, exist in plant tissues in more than one form. In the course of the present investigation, methods for the extraction of the less readily diffusible auxins have been studied. The auxin so extracted was isolated and identified.

The early experiments of Went (1928) proved that the substance influencing cell elongation in the *Avena* coleoptile could be separated from the plant by diffusion into agar. Later investigators proposed other methods of effecting extraction, which may be classified according to general type as follows:

- (1) Solvent extraction (summary by Avery [1939]; Avery, *et al.* [1940]).
- (2) *In vitro* chemical or enzymatic treatment followed by solvent extraction.
 - (a) Alkaline hydrolysis (Kögl, *et al.*, 1934a and b; Avery, *et al.*, 1941; Haagen-Smit, *et al.*, 1941).
 - (b) Lipase hydrolysis (Kögl, *et al.*, 1933b).
 - (c) Chymotrypsin (Skoog and Thimann, 1940).
- (3) Biological digestion (Kögl, *et al.*, 1933b).

Application of the extraction methods of the various investigators has indicated that the auxin present in plant materials exists in at least two forms: a readily diffusible or "free" form and a less readily extractable or "bound" form. Recently, Thimann and Skoog (1940) have made further distinctions between different types of extraction behavior in the materials which they studied (*Lemna*, *Nicotiana* callus, *Phaseolus* nodules, *Avena*). Their tentative classification of the forms in which they consider the auxin to be present is as follows:

- (1) *Free*, readily diffusible.
- (2) *Naturally bound*, apparently an auxin-protein complex.
- (3) *Reversibly fixed*, becomes non-extractable upon drying and is extractable upon rewetting.

Different plant materials may behave quite differently as regards the extraction of auxin, and it has

been impracticable heretofore to formulate a simple, inclusive, quantitative extraction method. For example, Thimann and Skoog found that repeated solvent extraction upon *Lemna* continued to remove auxin but that this was not the case with *Avena* coleoptiles. They concluded, as did van Overbeek (1941), that solvent extraction recovers, in the case of *Avena*, only a fraction of the total auxin which the coleoptile tips would have yielded had they remained alive. Skoog clearly showed in *Avena* seedlings the existence of an inactive substance originating in the seed and activated at the coleoptile tip. Van Overbeek (1941) studied the relative amounts of auxin obtainable from *Zea* and from *Avena* coleoptile tips by exhaustive diffusion as compared to those removed by exhaustive solvent extraction. He found that "potential" auxin, as measured by exhaustive diffusion, is considerably greater than that obtainable by complete extraction. The "potential" auxin he ascribes to continued formation from precursor. Further, Went (1942) has studied the movement of precursor to the tip ends of decapitated *Avena* coleoptiles and has found an increasing accumulation of precursor. The combined evidence of these investigators indicates that at least one precursor is something other than a non-motile auxin-protein complex.

Still another factor in the problem of the forms of auxin in plant materials has been introduced by the recent work on inhibitor substances. Evidence for a definite inhibitor substance was first presented by Stewart, Bergren, and Redemann (1939). Further experiments carried out by Redemann showed that an alkaline hydrolysis of the purified inhibitor substance, obtained from young radish plants, produces a substance effecting negative curvatures in the *Avena* test, rather than the positive curvature characteristic of the original inhibitor. Evidence was obtained indicating that the growth substance so formed was indole-3-acetic acid; consequently, the radish inhibitor may be considered as a "potential" auxin source. Goodwin (1939) and Larsen (1939) have also published data indicating the existence of growth inhibitors in plant extracts.

¹ Received for publication February 23, 1942.

In addition to the problem of the form of auxin in plant materials, the question of the identity of the active substance or substances is of interest and importance. Certain identification must be based upon actual isolation in pure condition of the physiologically active substances. However, a number of differentiation tests have been devised and used, which, while not serving as means of definite identification, have had important bearing upon phytohormone studies. A frequently used differentiation test has been that of Kögl, Haagen-Smit, and Erxleben (1934a), which depends upon the differing stabilities of auxin-a, auxin-b, and indole-3-acetic acid towards boiling with acid and boiling with base. In most cases, however, the applications of this method have been to such relatively impure extracts that uncertainty regarding the validity of the results has been inevitable. Another differentiation method is the diffusion-constant method used by Went (1928).

The present investigation was undertaken with two purposes in mind: first, to devise a satisfactory inclusive auxin extraction method, and second, to identify the physiologically active substances so extracted. Such an extraction method is one which would extract, by an *in vitro* method, auxin in all its forms, regardless of the particular entities concerned. Further, it is desirable that the extract so prepared be in a form suitable for identification of the active substances by isolation.

The extraction process finally adopted grew out of work involving the biological digestion method of Kögl, Haagen-Smit, and Erxleben (1933b). This method, although of necessity limited in application, is capable of giving the highest hormone content of a plant material as compared to other methods. In this procedure, the human organism is used to extract the growth substance, the extracted auxin being found in the urine. The method had its origin in the observation that the urine showed a peak in auxin activity about two hours after each meal and that during days of fasting the urinary auxin activity remained constant. Experiments have indicated that the rise in the auxin activity of the urine could be related directly to the ingestion of foodstuffs, i.e., to auxin arising from the ingested material.

In the present studies, biological digestion of wheat was found to give a yield of auxin higher than that obtained by other extraction methods. This yield was then used as a criterion of the highest amount of growth hormone available from wheat. A systematic study of *in vitro* methods for obtaining auxin yields comparable to those obtained by biological digestion was then carried out. Having arrived at such an *in vitro* procedure, the method was applied to other materials, and isolation and identification studies of the active material were undertaken.

PROCEDURE.—Assay method.—All auxin determinations were made by the standard *Avena* test (Went and Thimann, 1937, pp. 27–42), using an interval of three hours between decapitations and a period of ninety minutes between blocking and photographing. The minimum number of *Avena* test plants used

for any single determination was twelve, although in many instances twenty-four or thirty-six plants were used.

In every case the data presented are the results of a single test. Each test, however, was preceded by a number of preliminary experiments to establish the maximum and minimum range for each substance.

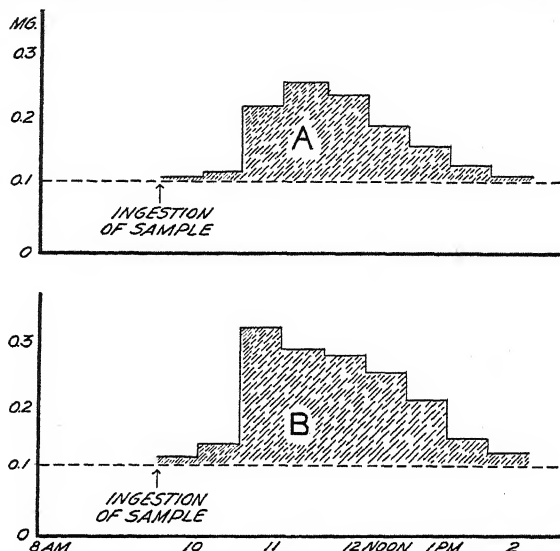

Fig. 1. Half-hour excretion of auxin in terms of indole-3-acetic acid. The excretion of auxin is determined every half hour after the ingestion of the sample. The shaded area represents the total amount of excreted auxin due to the sample, A, from medium hard wheat yielding 6.5 mg. per kilogram of wheat, B, from soft wheat yielding 9.8 mg. per kilogram of wheat. The dotted line represents the fasting level in each case.

Biological digestion method.—In agreement with the observations of earlier investigations, it was found that the increase in urinary auxin activity was several times more than could be accounted for by assay of the foodstuff. The desirability of duplicating this effect *in vitro* was evident, and consequently experiments towards this end were undertaken.

As a first step in this direction, the maximal amounts of auxin obtainable from wheat by the biological digestion method were determined. A typical experiment is outlined as follows:

1. Urine accumulated overnight passed and discarded at 5:30 a.m.
2. 100 cc. water ingested at 6:00 a.m. and a like amount each half hour thereafter until 1 p.m.
3. First urine sample collected at 7:30 a.m., and subsequent samples collected at half-hour intervals until 1:30 p.m.
4. 100 grams of soft white wheat kernels ingested at 9:00 a.m.
5. The volume of the urine at each collection was measured, and the sample was then diluted sufficiently to give a curvature of 5 to 15 degrees in the standard *Avena* test.

Assay of the separate urine samples collected showed that the peak of the yield of auxin was ob-

TABLE 1. Auxin yields from "medium hard" wheat upon treatment with enzymes.

Enzyme ^b	pH-Maintained	mgm./ml./Enzyme used	Auxin yield ^a mgm./kgm. wheat

^a In terms of indole-3-acetic acid, calculated according to van Overbeek (1938b).

^b Buffered to optimum pH for each enzyme, with phosphate-acid phosphate buffer and held at 35°C. for thirty hours.

tained within two to two and a half hours after ingestion of the wheat (fig. 1). The total auxin yield as obtained by this method was found to be 9.8 mgm. of active material, calculated as indole-3-acetic acid, per kilogram of ingested wheat. This figure has been corrected for the average total yield obtained in the urine in corresponding experiments in which wheat was not ingested.

Since the ingestion of tryptophane in the course of similarly performed experiments showed no auxin increase above the average level for a fasting day, oxidative deamination of tryptophane proceeds too slowly to contribute appreciably to the above results. For this reason it is believed that the above value of 9.8 mg. per kgm. represents free, bound and/or precursor auxin in the whole wheat ingested. The value 9.8 mgm./kg. was obtained for "soft" wheat only. A large variation was found in the maximum yields obtainable from different wheats, "medium hard" wheat giving a maximum yield of 6.5 mgm./kgm. (fig. 1). (The terms "soft" and "hard" are used in reference to low and high protein content of the wheat.) It is of interest to note that a solvent extraction method (water, ether) will yield 0.5 to 1.0 mgm. of auxin per kgm. of soft wheat, and a scarcely detectable amount from "hard" wheat.

This method served as a criterion for the highest auxin yield from whole wheat. *In vitro* studies upon this material were then undertaken.

Extraction and enzyme hydrolysis.—Three methods of attack were used: (1) search for suitable extractants; (2) use of enzymes; and (3) treatment with acids and bases. The efficiency of each method employed was judged by the quantity of auxin obtained in relation to that obtained by the biological digestion method.

Butyl alcohol saturated with water served relatively well for extraction, though not as well as either the purified ether method of van Overbeek (1938a) or the absolute alcohol method of Avery (1939). Since a large number of other extractants tried

proved even less successful, an enzymatic method of liberation of auxin was then tried.

Several enzymes were investigated, including some of those commonly found in the digestive tract; namely, ptyalin, pepsin, chymotrypsin, lipase, amylase, urease, papain, tyrosinase, taka diastase, and, in one case, the mucosa pylorus of the rabbit, a source of mixed enzymes. Each wheat sample, together with the enzyme under trial, was incubated for twenty-four hours at the optimum pH of the enzyme in question at a temperature of 35°C. The sample was then centrifuged, and the clear supernatant liquid was tested for its auxin content.

Of the enzymes tried, only chymotrypsin, a gift to this laboratory from Dr. Northrop, gave a yield representing any significant increase over a blank determination. This increase is probably associated with hydrolysis due to the alkaline condition of the medium, as is indicated in the following examination of the pH effect. Table 1 shows the effects of the various enzymatic treatments.

Alkaline hydrolysis.—Kögl, Haagen-Smit, and Erxleben (1934b) found that sodium ethylate smoothly hydrolyzed the bound hormone in corn oil. Hydrolysis by this scheme was carefully investi-

TABLE 2. Effect of pH on auxin yield. (Room temperature, 48 hours.)

gated to ascertain if whole wheat might respond in a similar manner, but without success. However, an extension of this method did prove to be suitable, namely, an alkaline aqueous hydrolysis, as described by Avery and co-workers (1941). Haagen-Smit, Leech, and Bergren (1941) showed a similar increase in extractable auxin by use of an alkaline hydrolysis.

Table 2 shows a typical experiment upon the effect of pH on the quantity of auxin liberated from a sample of medium soft wheat, as measured by the standard *Avena* technique.

The optimal pH having been found to be at 10.5, the effect of other variables was studied.

In table 3 is shown a typical experiment upon the effect of time on the quantity of hormone liberated at pH 10.5, as determined by the standard *Avena* test.

90.0	4.40

^a Computed as indole-3-acetic acid.

As the effect of increased temperature (table 4) was of small magnitude, room temperature was adopted for routine study of the alkaline hydrolysis effects. Above 60°C., the auxin yield was considerably less, especially over the long periods of hydrolysis employed.

^a Computed in terms of indole-3-acetic acid.

After considering the results obtained by treating dormant tissues such as wheat, corn, and oat kernels, under various conditions, the following procedure was selected as a method giving results comparable to the yields of the biological digestion method.

Method.—Twenty-five grams of dry whole wheat are placed in a 125 ml. heavy walled Pyrex glass

centrifuge bottle and soaked for four hours with 50 ml. of NaOH solution adjusted to pH 10.5. At the end of this period, the contents are emptied into a mortar together with half the weight of specially cleaned sand (washed in steam, alkali, acid, and water, then dried). They are thoroughly ground and then carefully transferred to the original centrifuge bottle, the residue remaining with the mortar and pestle being washed into the tube to make a final volume of 100 ml. The pH is readjusted to 10.5 by dropwise addition of a concentrated solution of NaOH. One ml. of toluene is added, and the bottle is stoppered with a cotton plug and is set aside out of direct light at room temperature (about 20°C.) for a period of 48 hours. The pH is readjusted to 10.5 ten hours after starting the experiment. This operation is repeated at four-hour intervals during the hydrolysis. At the end of forty-eight hours, the mixture is adjusted to pH 6.5 and centrifuged. The clear supernatant liquid is appropriately diluted for assay by the *Avena* test.

ACID-BASE SENSITIVITY OF THE ALKALINE HYDROLYSATE.—Although it was understood that the acid-base sensitivity test, as outlined by Kögl, Haagen-Smit, and Erxleben (1934a), would not serve to determine with certainty the identity of the auxin liberated upon alkaline hydrolysis, experiments were made in this direction to obtain preliminary information.

A typical experiment may be summarized as follows:

- Two 20-gram portions of yellow cornmeal were mixed with 200 ml. of water. One of these mixtures was held as a control; the other was adjusted to pH 10.5 and held there for the hydrolysis period of forty-eight hours.
- At the conclusion of this period, the alkaline hydrolysate was divided into three portions, treated as follows:
 - One portion was held as a control.
 - One portion was mixed with an equal portion of 10 per cent sulfuric acid and boiled under reflux for three hours. The solution was then neutralized for *Avena* testing.
 - The remaining portion was mixed with an equal portion of 10 per cent potassium hydroxide and boiled under reflux for three hours.
- The following results were obtained upon assay for auxin by the *Avena* procedure (the figures represent auxin yield in terms of mgm. indole-3-acetic acid per kgm. of cornmeal):
 - Cornmeal control..... 1.8 mgm.
 - Cornmeal hydrolysate control..... 13 mgm.
 - Acid treated cornmeal hydrolysate..... 0 mgm.
 - Base treated cornmeal hydrolysate..... 10 mgm.

It is to be seen that the auxin activity is lost upon acid boiling (within practicable testing dilution limits) and is substantially retained with the treatment by base. This behavior is indicative of the presence of indole-3-acetic acid in the hydrolysate. These results are consistent with the findings of Avery, *et al.*, 1941.

Despite the results of these experiments, it was considered desirable to conduct the isolation work

toward the isolation of auxin-a and -b, with indole-3-acetic acid as an auxiliary aim, rather than toward an isolation directed solely at the recovery of indole-3-acetic acid.

ISOLATION WORK.—Yellow cornmeal, fresh from milling was used as a convenient source material for isolation and identification studies, after preliminary experiments had been carried out in the manner previously described for wheat. A typical experiment may be summarized as follows: standing at pH 10.5 for forty-five hours gave 13.0 mg./kgm. (calculated as indole-3-acetic acid) as against 1.8 mgm./kgm. in a control sample standing with water at pH 7.0.

For isolation purposes, the obvious method for liberation of auxin from the cornmeal would be essentially the application of hydrolysis with a dilute aqueous alkaline solution as described in the above testing procedure. However, it proved to be more convenient for large scale extractions to carry out the hydrolysis at pH 10.5 in an alkaline 50 per cent acetone-water (acetone purified by distillation over alkaline KMnO_4). The pH was adjusted to 10.5 with 6N NaOH, and every six hours during the hydrolysis period the mass was stirred and the pH readjusted to 10.5. After fifty hours the mass was pressed, washed, and the collected filtrates were filtered through a layer of sodium chloride. This filtration had as its primary purpose the separation of the filtrate into an acetone phase and a water phase. It had the further advantage of breaking down fat-water emulsions, as well as of clearing the mixture of extraneous materials.

The aqueous portion was washed five times with acetone, the volume of acetone in each washing being one-fourth that of the water. After combining the first acetone phase with the acetone washings, the bulk of the acetone was distilled off at atmospheric pressure, and the residue was evaporated under vacuum to a volume suitable for ether extraction. The washed water layer was discarded, after being found by assay to be free of auxin.

Two large scale isolations were carried through this procedure, the first (lot number one) being upon 270 kilograms of cornmeal and the second upon 45 kilograms. Lot number 1, starting with the acetone soluble residue, was carried through the original isolation plan of Kögl, Haagen-Smit, and Erxleben (1933a) for the isolation of auxin a and b from urine concentrates.

In the course of the isolation from lot number 1, the ligroin (90° – 120°) extraction was made more thorough than has been customary in previous work (in this case twenty-one refluxings of twenty minutes, each treatment of the 10-gram residue being with 500 ml. ligroin). The soluble fraction weighed 1.6 grams and contained 102 mgm. of active substance calculated as indole-3-acetic acid; the insoluble weighed 5.5 grams and contained 160 mgm. of active substance, computed as indole-3-acetic acid. Upon lactonization (heating with a 1.5 per cent solution of hydrogen chloride in anhydrous methyl

alcohol), the bulk of the activity of the ligroin insoluble fraction was lost, and from the lactonized ligroin soluble fraction pseudo-auxin-a finally was isolated following the procedure of Kögl, Haagen-Smit, and Erxleben (1933a). As has been reported (Haagen-Smit, *et al.*, 1941) this crystalline material melted at 196 – 7°C ., with sintering beginning at 173°C . Kögl, Koningsberger and Erxleben (1936) give the melting point of pseudo-auxin-a as 193 – 4°C . with sintering at 176°C . This points to the presence of some auxin-a in the original starting material, which rearranged to pseudo-auxin during the isolation procedures.

In view of these results, it was decided to modify the procedure to include an even more exhaustive ligroin extraction as early in the procedure as possible. Accordingly, the second isolation was undertaken. The procedure is summarized in the following table:

SCHEMATIC DIAGRAM OF SECOND CORNMEAL ISOLATION.—(The first figure in the bracket following the fraction is the weight of the fraction and the second is the amount of auxin, calculated as indole-3-acetic acid.)

Yellow cornmeal	45 kgm.	(900 mg.)
↓ Alkaline hydrolysis	50 per cent acetone-water	
Extract		
▼ Salting out—acetone washing of aq. layer		
Residue (Acetone soluble)		
▼ Extraction with ether		
Residue (Ether soluble)	123 gm.	(200 mg.)
↓ Fractionation with bicarbonate solution and extraction of acid fraction with Pet. Ether (30 – 60°C .)		
Insol. fraction	15 gm.

Neutral fraction	326 mg.	10 mg.
▼ Hydrolysis at room temperature with 3N KOH		
Acid fraction	250 mg.	7 mg.
▼ Extraction with Xylene		

Soluble fraction 122 mg. 7 mg.
 ↓ Crystallization began after standing 3 months at 2°C.
 ↓ Recrystallization after standing twelve months at 2°C.
 Crystalline, colorless plates MP. 164–5°C. No melting point depression on mixing with synthetic indole-3-acetic acid. (MP. 164–5°C.) Crystals identified as indole-3-acetic acid.

DISCUSSION.—By isolation and identification three auxins have been shown to be present in higher plants, *nl.* auxin-a and -b and indole-3-acetic acid. Auxin-a and -b were isolated by Kögl, *et al.* (1934b), from corn oil and from sprouted barley (malt). Usually these materials contain very little auxin, which can be extracted by treatment with water. After trial of many samples Kögl and co-workers were fortunate in obtaining several hundred kgs. of malt and barley with exceptionally high auxin content from which auxin-a and -b were isolated. Attempts to produce artificially malt with such a high auxin content failed, although it was observed that the amount of water-extractable auxin increased with the time of germination. We have tried here to obtain oils or seeds with similar high free auxin content, but did not succeed. Attention was then focused upon the diet experiments carried out by Kögl, *et al.* (1933b), whereby the auxin excreted was much more than could be accounted for on the basis of ingested food materials. Our diet experiments showed that whole wheat produced this increased yield on biological digestion, whereas with solvent extraction only a fraction of the amount excreted in the urine could be determined. Studies upon the *in vitro* duplication of the effect led to a procedure of alkaline hydrolysis giving the same yields of auxin as the biological digestion experiments. An extension of this process using aqueous alkaline acetone as hydrolyzing agent furnished a starting material for isolation work. Although a considerable increase in total auxins results from the hydrolysis, the material is still not comparable to the auxin-rich corn oil and barley available to Kögl and co-workers. This hydrolyzed material contains many more impurities than the extracts containing the free auxins. Losses were also due to a tendency of the solution to form emulsions. This behavior increased the time necessary for the extractions considerably, thereby reducing the amounts of auxin-a and -b, since both substances are known to rearrange readily with the formation of the pseudo-auxins. Another important factor in these losses is the hydrolysis under alkaline conditions. Treatment with alkali decomposes both auxin-a and -b, whereas indole-3-acetic acid is stable under these circumstances. Therefore, it is not surprising that auxin-a could not be isolated from this hydrolysate; we did, however, obtain a small amount of the inactive pseudo-auxin-a showing the presence of auxin-a in the original material. The major portion of the auxin activity in hydrolyzed corn appears to be due to indole-3-acetic acid as concluded from stability tests to alkali and acid. This is in accordance with the work of Avery, *et al.* (1941). The

presence of indole-3-acetic acid was then definitely established by isolation and characterization by melting point and mixed melting point with synthetic material. From the work of Kögl, *et al.*, we have to conclude that in corn with exceptionally high free auxin content the water-extractable auxins contain a considerable amount of auxin-a and -b. The free and bound auxins in corn consist largely of indole-3-acetic acid and some auxin-a.

When we want to determine the presence and type of the free and bound auxins, isolation followed by characterization is in most cases not possible through lack of material or low auxin content. In such cases we have to satisfy ourselves with less specific methods, such as molecular weight determination by diffusion and acid and base sensitivity tests. In this respect the difference in physiological effect of auxin-a and -b and indole-3-acetic acid might be of importance. Experiments by van Overbeek (1936) with crude auxin-a preparations, which were later confirmed and extended by Koningsberger and Verkaarik (1938) with pure auxin-a, showed that decapitated oat seedlings responded with decreased growth to light if auxin-a is applied and not when the plants elongate under the influence of indole-3-acetic acid. This behavior found an explanation in the different chemical structure of auxin-a lactone and indole-3-acetic acid. Auxin-a lactone, which is in water solution in equilibrium with auxin-a, is, under influence of light, changed into the physiologically inactive lumi-auxin-a lactone (Oppenoorth, 1939). Such a change is not possible in the molecule of indole-3-acetic acid.

SUMMARY

A method of auxin extraction comparable in completeness of extraction to the *in vivo* biological digestion method is described as being a hydrolysis at pH 10.5 for forty-eight hours at room temperature.

Isolation of the auxin extracted from cornmeal by this method yielded crystals melting at 164–165°C., identified as indole-3-acetic acid.

Pseudo-auxin-a was isolated from the hydrolyzed cornmeal, which shows the presence of auxin-a in the original material.

THE PRODUCTION OF SPORIDIA OF *CRONARTIUM RIBICOLA* ON CULTIVATED RED CURRANTS IN RELATION TO INFECTION OF WHITE PINE¹

Walter H. Snell

IN a previous paper (Snell, 1941b) the results of studies of white pine near cultivated red currants were presented, showing that such pines became infected very rarely by sporidia of *Cronartium ribicola* and only at short distances, unless there were also wild *Ribes* within infecting distance. The present paper deals entirely with the blister-rust pathology of garden currants as compared with some other species of *Ribes*, its relation to the control of potential sporidium production and the determination of distances at which pines can be infected from these species.

For at least twenty years, it has been recognized that cultivated black currants are much more dangerous to white pine² and at much greater distances than are other eastern species of *Ribes*, but there has been no thorough-going study of the reasons for this. The only direct answer that is more than a suggestion or a vague generality has been hidden in a little-circulated and poorly known publication (Spaulding, 1920, p. 11), and although blister-rust workers have tacitly assumed its application to the question (*cf.* York, Snell and Rathbun-Gravatt, 1927, p. 509) no

attempt has ever been made to apply this answer to other species of *Ribes*, let alone the red currants³ and the important red-currant problem.

One answer to this question has been that the greater susceptibility of *R. nigrum* results in the formation of teliospores and sporidia of greater vigor than is possible upon other species of *Ribes* which are less congenial to the rust. Spaulding (1922b, p. 224) stated that the telia on *R. nigrum* are "of maximum vigor in germination and production of sporidia." From further work (Spaulding, 1925, and Spaulding and Rathbun-Gravatt, 1925 and 1926), there seems to be little doubt that this is true, and it is quite likely that the same is true of the vigor of germination and ability of the sporidia to infect (York, Snell and Rathbun-Gravatt, 1927, p. 508, and Lindgren and Chapman, 1933), but the evidence is neither abundant nor clear, nor as to the latter point, proof against justifiable criticism. Unless the differences in virility of the teliospores and sporidia should be very much more pronounced than the evidence indicates, it is difficult to understand why the

³ In this paper, as in those papers preceding this one (Snell, 1941a, footnote 1, and Snell, 1941b), "red currants" refers to the garden red currants of hybrid origin customarily referred to *Ribes sativum* (Rchb.) Syme. Similarly, by "black currants" is meant the European black currants, *R. nigrum* L. The swamp red currant, *R. triste* Pall., and the wild black currants, *R. americanum* Mill., are not treated in this paper.

¹ Received for publication February 28, 1942.

² The phrases "danger to white pine," "dangerous distances," "*Ribes* causing infection of white pine," are used to express as concisely as possible the infection, or possibility of infection, of white pine by sporidia of the blister-rust fungus and the distances to which these sporidia can be carried to infect pines.

sporidia from *R. nigrum* will infect large percentages of pine at 5,000 to 6,000 feet and those from the wild gooseberries few or none beyond 800 to 900 feet under similar circumstances, especially since the evidence from most of the experiments so far performed⁴ indicates that the sporidia from any species of *Ribes* can withstand exposure to drying and sunlight for periods long enough to cover their passage over several to many miles through the air (Spaulding, 1925, and Spaulding and Rathbun-Gravatt, 1926).

Another explanation as to why cultivated black currants are dangerous at greater distances than other species of *Ribes* is based upon the tremendously larger volume of sporidia produced at a given location on *R. nigrum*, in consequence of which some viable sporidia will be carried to a distance greater than is possible from the smaller volumes of sporidia produced on other species of *Ribes*. In other words, this idea suggests the possibility of a more or less direct relation between numbers of sporidia produced at a given source and the distance to which the sporidia will be carried by the wind. In fact, Pennington (Spaulding, 1920) early formulated this explanation as follows: "... under given conditions the number of infections in pine varies directly with the amount of *Ribes* leaf surface and inversely as the square of the distance from *Ribes*." Obviously, "amount of *Ribes* leaf surface" is meaningless, but implies the number of sporidia produced on the infected leaf surface. Pennington's statement, therefore, means that the distance of dissemination of the sporidia varies directly with the square root of the number of sporidia produced on a given species of *Ribes*.

Whether or not this statement of the relationship is valid, whether the relationship is one of square roots or is a linear one, will not be argued here. There is at least another possibility that must be taken into consideration, if it is not the most important consideration. It is, in a way, a corollary of the preceding mathematical explanation, and emphasizes more than mere numbers of sporidia produced, the volumes of *viable sporidia necessary for infection*. It may be, and very likely is, true that there is a "threshold" or "quantum" relationship between sporidium production and infection. It is certain that huge numbers of sporidia are produced for every infection of pine. It is possible that wild gooseberries do not produce enough sporidia to provide the proper quantity for more than sporadic infection at distances over 900 feet. It is possible that in the case of

⁴ In some very early experiments, York was unable to obtain germination of sporidia caught 2,400 feet from black currants, and he also found that sporidia from this same source remained viable less than ten minutes at a relative humidity of 90 per cent between 22°C. and 25°C. (Spaulding, 1920, p. 11). Spaulding and Rathbun-Gravatt, however, later showed that in no tests did sporidia from any host fail to germinate after one-half hour at any saturation deficit, and in most tests, sporidia from all hosts germinated after drying for periods of nine to twenty-six hours (Spaulding and Rathbun-Gravatt, 1926).

In connection with the general problem, McCubbin's work (1918) on the rate of fall of spores should be kept in mind.

red currants this threshold number or quantum is not even reached.

No work has been done by the writer on the vigor or germinability of the sporidia, but a study has been made of volumes of sporidia produced by the different species of *Ribes*. This has involved a detailed study of the number of leaves to the bush and to the plot, the total leaf area of bushes and groups of bushes, the number of telia and hence of sporidia produced, in other words, the volume of infective material endangering white pine, or what has been called the "hitting power" of different species of *Ribes*.

BUSH SIZE AND LEAF AREA.—Red currants.—Leaf counts have been made of about seventy-five patches of red-currant bushes. Bushes in very poor condition may have as few as 200 leaves. A few bushes have been found with as many as 22,000 leaves. Many patches will have bushes with 10,000 to 15,000 leaves each, while the average garden bush was found to bear 3,000 to 10,000 leaves. Two large canes on a bush in Port Henry were found to bear 1069 and 1,137 leaves respectively.

The areas of individual leaves vary from a fraction of a square inch up to 14.3 square inches.⁵ The average of many measurements was 3.346. Some bushes will have a large number of average or small-sized leaves, and others a smaller number of very large leaves. Any bush will have large leaves on the new canes and smaller leaves on the older canes.

Black currants.—The number of leaves borne by black-currant bushes is about the same as for red currants, up to 20,000 or perhaps more on very large, vigorous bushes, with the average bushes bearing 4,000 to 10,000 leaves. The areas of individual leaves measured in recent years were found to vary from 1.5 to 14.3 square inches, with an average of 4.136. Spaulding (1922b) stated that this species produces an area of leaf surface that is maximum for the genus (that is, maximum for eastern species).

The leaf areas of all the bushes available from 1936 to 1938 ranged from 2,606 to 33,770 square inches, with the average bushes having areas of 16,000 to 25,000 square inches.

Wild gooseberries.—Bushes of *R. cynosbati* L. counted from 1935 to 1938 ranged from 15 to 20 leaves up to 18,000. Good-sized bushes averaged 7,000 to 9,000 leaves, while very large ones might have 50,000 or more leaves.

The areas of individual leaves vary from 0.22 to 6.83 square inches, although leaves over 2 square inches in area are rare except on new shoots growing in the shade. In the open, the leaves will average, on different bushes, from 0.45 to 0.75 square inches; in the shade, as much as 1.4 square inches.

Good-sized bushes have been found to have a total leaf area of 5,000 to 6,000 square inches, with the largest probably having 12,000 to 25,000 square inches.

⁵ The areas of large numbers of leaves were obtained from curves of area against width, prepared for four species of *Ribes* after the manner of Caruthers (1929).

In a half acre of one pasture that could be taken as a typical unit because of the distribution of the bushes as well as their concentration, there were 28 bushes with a total leafage of 93,000, an average of 3,320 leaves per bush. In 1938, the largest leaves in this pasture were 3.5 square inches, but few were more than 1.4 square inches in area, and the average of several bushes was 0.73 sq. in. The total leaf area for the half acre of pasture was 67,890 square inches. In 1940, leaves from these same bushes averaged only 0.455 sq. in. in area.

Bushes of *R. rotundifolium* Michx. usually have more leaves of smaller size (in a rough ratio of 11 to 6 or 8) and a smaller total leaf area per bush than is the case with *R. cynosbati*. Quite ordinary bushes have 15,000 to 22,000 leaves each, while large bushes 6 feet high or over may have 50,000 leaves.

The largest leaves found in 1938 had an area of 1.6 square inches, in 1940, 2.66 square inches. In 1938, the average of several hundred leaves was 0.446 sq. in.; in 1940, 0.415 sq. in. The total area of ordinary bushes ran from 7,000 to 11,000 square inches, of very large ones up to about 25,000 square inches.

DEGREE OF INFECTION⁶.—*Red currants*.—In the past twenty-five summers of study of the white pine blister-rust from Maine to Minnesota, the writer has never seen what he could term a heavily infected red currant bush. By "heavy infection" is meant the maximum development of the blister-rust upon completely infected leaves of the European black currant, which should be taken as a standard of comparison. While some varieties of red currants are very susceptible (Hahn, 1930, and Spaulding, 1922a) and while there is no reason why some individual bushes of other varieties should not be susceptible to attack, it is a fact that cultivated red currants in general are not heavily infected by the blister-rust fungus (Snell, 1941a and 1941b). What is usually called a "heavily infected" bush is heavily infected *only for red currants*, but never in the writer's experience in the terms defined above. In blister-rust discussions, black currants, wild species of *Ribes* and cultivated currants have subconsciously been considered as belonging to different categories in this respect. It is certain that when red currants have been described as "heavily infected," the describer never intended to convey the impression that they were infected to the degree common on black currants. The same has too often been true also with respect to wild gooseberries.

In 1937 in the counties around Syracuse and Rochester, 26 plots of red currants with a total of 2,928 bushes (2,715 in one plot) were found to be infected as follows: 6 bushes rather heavily infected for red currants (4 per cent to 6 per cent of the entire leaf area); 33 bushes moderately infected for red currants (1 per cent to 4 per cent); the remaining 2,889 only slightly if at all infected. By "slightly infected"

⁶ Throughout this paper, degree of infection of leaves, bushes or lots of bushes is in terms of total discolored area against total leaf area in each case, expressed as percentage.

is meant to the extent of only a few infection spots per bush—5 to 300, or one spot to 50 to 3,000 leaves. The infection percentages of the various plantings ran from 0.0001 per cent to 2 per cent (on a total area basis), with an average of 0.77 per cent for all of them. The average infection a bush was 0.0432 per cent, including the 2,715 bushes in one plot, 0.743 per cent without them.

In the eastern Adirondack region, red currants have been found in 21 gardens, for a total of 343 bushes. Of these bushes 4 have been found heavily infected *for red currants*, 2 moderately infected, and the remaining 337 not at all infected or with only a few spots to the bush. Nine of the plantings were not at all infected and the heaviest infection was 1.17 per cent. The average infection of the plantings was 0.15 per cent and of individual bushes was 0.131 per cent.

While individual leaves may have 75 per cent of their areas covered by blister-rust spots, the most heavily infected bushes in gardens have been from 5.5 per cent to 6.6 per cent infected. The more lightly infected bushes have been 1/4000 of one per cent to 1 per cent or 2 per cent infected. On the most heavily infected garden bush encountered in these studies (6.6 per cent), 0.8 per cent of the leaves were 75 per cent infected, 3.2 per cent were 30 per cent to 50 per cent infected, 13.7 per cent were 10 per cent to 29 per cent infected, 31.5 per cent were 3 per cent to 9 per cent infected, 25.1 per cent were 0.5 per cent to 2 per cent infected, 4.3 per cent had one spot per leaf and 21.4 per cent had not a single spot.

Black currants.—The leaves on bushes of these plants will have up to 97 per cent of their areas infected, with most of the leaves 75 per cent to 95 per cent infected. Of the total leaf area of a bush, between 75 per cent and 80 per cent will be infected and ultimately⁷ bear telia. Furthermore, all of the bushes in a garden will be equally heavily infected. Resistant black currants have been rare in the writer's experience.

Wild gooseberries.—The infection of individual leaves of both prickly and smooth gooseberries has been found to vary from a fraction of one per cent to 77 per cent on ordinary pasture bushes, with relatively few leaves over 25 per cent infected. On small bushes of one or two young shoots, growing in the shade, the amount of infection can be much higher. For example, one "bush" consisting of one shoot 10 inches high growing in a close pine stand had 14 leaves varying in area from 1/20 to 1/3 of a square inch, which were 56 per cent to 100 per cent infected, with a total for the "bush" of 73 per cent infection.

On the most heavily infected sizable bush found in the last few years, individual canes had from 16 per cent to 35 per cent of their leaf areas covered with telia, the average for the bush being 28 per cent.

No exact counts or measurements have been made of all the bushes in a pasture, but on the basis of ac-

⁷ In the west, Kimmey (1938, p. 317) gives 65 per cent of the lower leaf surface infected and 60 per cent bearing telia, as "estimates based on lighter rust infection conditions, some of which gave values as great as those given in the table for this species."

curate data obtained for the leaves of a few bushes, it has been estimated that a fair average for a pasture as a whole would be 15 per cent to 20 per cent of the total leaf area bearing telia under the most favorable conditions of recent years.

FACTORS REDUCING THE PRODUCTION OF SPORIDIA ON RED CURRANTS.—It is seen from the foregoing that while individual leaves of red currant may be about as heavily infected as the leaves of other species, the maximum infection of bushes is comparatively low and for the vast majority of them is very low. Further, even this condition of low susceptibility does not give a true idea of the potential sporidium production, the infecting ability, for there are many factors at work limiting the total amount of infective material from red-currant bushes. These must be emphasized.

Number of infected bushes in a lot.—Whereas the bushes in a garden of black currants will all be uniformly infected, because resistant black currants are very rare, and a pasture of wild gooseberries can be and usually is quite heavily infected throughout, all the bushes in a garden⁸ lot of red currants, as far as has been observed, are never infected to the maximum degree possible for these plants. In fact, the writer has never thus far found a patch of red currant bushes with more than two of the six, or two of the twelve, bushes as much as 4 to 6 per cent infected. More often only one of the six or twelve bushes has been infected to this degree, or none at all (Snell, 1941a). York has also observed this condition in New Hampshire and western New York (letter of March 13, 1939).

High degree of resistance of mature leaves.—Hahn (1930, p. 107) pointed out that red currant leaves which have commenced to harden are not susceptible to infection. York has found the same to be true (same correspondence) and adds that if the leaves do become infected during the late hardening process, no uredia or telia are developed.

In a thorough study of three lots of red currants (one of them reported upon in detail elsewhere (Snell, 1941a)), the writer found that infection spots of late June and early July were 0.005 to 0.05 sq. in. in area, averaging 0.0112, while infection spots from the 10th of July on were rarely 0.005 sq. in. in area, were mostly punctate, with a single uredium, and averaged 0.0038 sq. in. in area. Over 100,000 infection spots were measured in this study.

Tendency of red currants to produce a single set of leaves per season.—Hahn (1928, p. 668) has noted the normal tendency of red currants to produce only a single set of leaves in the spring, and the absence of young leaves during the summer, contrary to the habits of wild gooseberries and *R. nigrum* (cf. Metcalf, 1924). In the writer's experience this is ordinarily true, but not universally so. While uninfected,

⁸ The words "in a garden" should be noted in this connection, because this generalization does not hold for planted red currants that have been abandoned and are allowed to grow uncared for (Snell, 1941a). The latter are almost always, if not always, more heavily infected than those in a well-cultivated patch.

lightly infected or moderately infected bushes put out no new leaves, the worst infected bushes will, on the other hand, sprout new shoots (Snell, 1941a).

Lowered viability of teliospores and sporidia.—Spaulding stated (1922a, p. 24) that resistant species and varieties produce a decreased number of uredia and telia and that the telia produced have a lowered viability. He also showed (1922b, p. 222) that telia on necrotic spots on *R. nigrum*, *cynosbati* and *rotundifolium* are not germinable. It is extremely likely that the same is true for *R. sativum*. York has observed that after the leaves attain a certain age, if uredia and telia are formed, they are poorly developed, have a low germination capacity and weak germ tubes or promycelia (same correspondence). Here again the writer has no new data of his own available for purposes of the treatment which follows, but the facts should be kept in mind when one considers the comparative numbers of sporidia produced by different species of *Ribes*.

Other important factors.—There are three other factors acting to reduce the total production of sporidia upon red currants which are probably the most effective of all. They are: (1) the early defoliation of red currant bushes as compared with other species of *Ribes*; (2) the necrosis of blister-rust spots; and (3) the reduced size of telia upon infection spots, whether the spots ultimately die or not. Some idea of the possibly very great, if not critical, importance of these factors may be obtained from the following brief statements: (1a) infected red currant bushes drop their leaves earlier than uninfected bushes; the more heavily infected they are, the earlier this occurs, with the most heavily infected leaves falling first; (1b) while infected red currant bushes may not be entirely defoliated until along in October, on the other hand most of the infected leaves are dropped before the middle of August; (2) in two patches of abandoned currants, the necrosis of spots was 75 per cent and 96 per cent before August first in 1940; (3) in these same two patches, 95 per cent of the telia were only 22 per cent to 50 per cent of the normal length. A complete discussion of these factors is given elsewhere (Snell, 1941a).

Recapitulation.—Even though at present precise or even general quantitative evaluation of the effect of these factors in reducing sporidium production on red currants is for the most part, if not entirely, infeasible or impossible, it is not difficult to realize that their several or total effects may be important or even decisive.

By way of further re-emphasizing these factors, it may be well to reproduce a quotation from Spaulding (1922b), which forcefully presents the situation in a negative manner. He says that *Ribes nigrum* "is dangerous as compared with other species because: (1) the plant is nearly maximum in height. (2) It is maximum in vigor of growth. (3) It produces new growth throughout the season. (4) It produces new shoots and leaves to a maximum lateness in the season. (5) It produces a maximum area of leaf surface. (6) It is more susceptible than any other species.

TABLE 1. Pathological specifications of comparable units of three species of *Ribes* and potential production of sporidia.

	1	2	3	4	5	6	7	8
	No. bushes	No. leaves	Area of leaves in sq. in.	% Infection	Area infected leaf surface (sq. in.)	Total no. telia for the lot	Total no. sporidia for the lot (in millions)	Rough ratio of nos. of sporidia in column 7
Black currants	6	30,000	124,080	77%	95,542	382,168,000	2,293,008	70
Prickly gooseberries	28	93,000	67,890	20%	13,578	44,128,500	264,771	8
Red currants	6	30,000	100,380	2.33%	2,340	5,616,000	33,699.6	1

(7) A maximum number of telia per unit of leaf area are produced upon this host. (8) These telia are of maximum vigor in germination and production of sporidia. (9) As shown by the above investigations, the telia produced on this host are of maximum longevity in the season."

POTENTIAL SPORIDIUM PRODUCTION OF COMPARABLE UNITS OF THREE SPECIES OF RIBES.—From the foregoing measurements of leaf areas and from counts of telia, and with a consideration of the only limiting factor at present susceptible of reasonably accurate evaluation for a general discussion, a determination of potential sporidium production has been calculated for comparable units of black currants, prickly gooseberries and red currants (table 1). Suppose that we take as these comparable units a row of six black currants, six red currants and the pasture half acre of prickly gooseberries discussed above using the data presented in the preceding sections of this paper.

The six black currants and the six reds (column 1) are certainly comparable, for these bushes are usually planted in sixes or dozens. The selection of something comparable in the gooseberries was difficult, because gooseberries occur scattered in fields and pastures, and as a rule not in clumps. There is of course no method at present known for determining the equivalent of the scattering or segregation of wild gooseberries in terms of concentration of cultivated *Ribes* (of bushes and hence of sporidia). It was thought, however, that the pasture half acre of gooseberries discussed above was a fair representation for our purposes, because the lack of concentration of sporidia characteristic of the cultivated bushes would be roughly equalled by the greater number of wild bushes. Further, this lot of gooseberries appears to be a fair sample, especially because the pines in the woods on all sides of it were infected to a degree quite typical of such locations in the Adirondacks—roughly 40 per cent bearing blister-rust cankers (Snell, 1928).

As to the number of leaves in column 2, bushes of 5,000 leaves were considered average for the black and red currants, even though in the writer's experience black-currant bushes are on the average larger and more vigorous than the reds [cf. Spaulding, 1922b, p. 224, items (1), (2), (3) and (5)]. The number of gooseberry leaves in the table is the one found by count and estimate.

The figures for area of leaves in column 3 are the result in each case of multiplying the number of leaves by a factor which is the average area obtained from the data discussed previously—for black currants 4.136, for red 3.346. For the gooseberries, the figure was taken directly from the data obtained in the pasture.

The percentages in column 4 have been discussed above. The only variation from those figures is that for the red currants, for which a maximum of 7 per cent was taken as fair, even though the largest percentage thus far actually found was 6.6 per cent. This was divided by three, because as mentioned, no more than two out of six or twelve have been found infected at any time in any garden.

The area of infected leaf surface (column 5) was obviously obtained by multiplying the figures in columns 3 and 4.

The numbers of telia (column 6) were obtained by multiplying the figures in column 5 by a factor found by actual counts of many leaves for each species. The averages in round numbers of telia to the square inch of infected leaf surface, from leaves of all degrees of infection, from different locations and in different seasons have been found to be as follows: black currants, 4,000; wild prickly gooseberries, 3,250; red currants, 2,400. Note that no account is taken of the possibility of a reduced number of telia on red currants, because of necrosis of spots, etc.

No work has been done by the writer on the relative numbers of teliospores or sporidia to a telial column produced by the different species. Taylor's 1,500 teliospores per column (1922) have been accepted as satisfactory for this discussion, and it has been assumed that each teliospore would form 4 sporidia. Hence, the numbers of sporidia in column 7 are obtained by multiplying the figures in column 6 by 6,000. No account has been taken of the factors which may, and usually do, reduce the numbers of sporidia produced by the resistant red currants, such as shortened season, necrosis of spots before telia are produced, short telia, and the reduced germinability of telia (Spaulding, 1922b).

Column 8 gives the rough ratio of the numbers of sporidia produced by the three species, under what are certainly only average or good conditions for black currants and prickly gooseberries, but the maximum conditions found for red currants. If one red currant bush were only 1 per cent infected and

five others were hardly infected, as is often the case, the ratio between the numbers of sporidia produced by the blacks and reds would be nearly 1,000:1. Or if the average infections of the red currants in the Adirondacks in 1936, 1937 and 1938, and in the western counties in 1937 were used, the ratios would be about 300:1; 1,000:1; 1,800:1 and 210:1, respectively. For some of the garden plots having the lowest degrees of infection (for example, one with 0.0001 per cent), the ratio is 1,625,000:1. In the latter case, fewer than four million sporidia would be produced on six red currants.

By a strange coincidence, if 6,600 feet (a mile and a quarter) is taken as a dangerous distance for black currants, a direct proportional calculation gives 750 feet as the dangerous distance for the prickly gooseberries, which accords with the common practise of eradication of *Ribes* other than black currants within 900 feet of pine. A similar calculation would give 95 feet for red currants, which, likewise strangely enough, is about what the writer believes is approximately correct, if not too great.

THE THRESHOLD (OR QUANTUM) RELATIONSHIP BETWEEN SPORIDIUM PRODUCTION AND INFECTION OF PINE.—This study is based upon data derived from damage-studies made in New York State (Snell, 1928, 1931a, and 1931b) and upon data from more recent studies of two species of wild gooseberries growing under different conditions and in different locations.⁹ From the latter data on total leaf area, total infection and potential sporidium production of wild gooseberries, three sets of data were selected (two for *R. cynosbati* and one for *R. rotundifolium*) to be used with the data from each damage-study plot. These three sets of data were used in order to avoid any arbitrary selection of a particular species of *Ribes* or any particular growth and infection conditions of the wild gooseberries, and in order to give some range to the resulting figures. It is true that such calculations will give only rough approximations or indications, because no definite data are available in regard to the wild *Ribes* on the damage-study plots during the period (roughly 1910 to 1923) in which most of the pine infections took place. The numbers and sizes of *Ribes* bushes on and around the plots are, however, known as they existed at the time of the studies and for a few years thereafter in each case. These figures were used in these calculations as if the same numbers of bushes and the same amounts of leaf-bearing stem had been on the plots during the entire period in which the pines were exposed to infection. It was assumed that the *Ribes* had been infected at a maximum throughout the infection period.

With these assumptions and in disregard of any considerations of the vicissitudes in the life-histories of the various *Ribes*-populations, calculations were made of the amount of infected leaf surface and of the possible number of sporidia produced on any

plot over the entire pine-infection period and this number was divided by the total number of permanently successful infections (the number of cankers), in order to obtain some idea of the number of sporidia required to produce a single canker. This final result was considered the threshold number or the quantum for the plot.

It is naturally expected that the figures so obtained would vary greatly, not only because the fundamental data are only approximately accurate, but also because the meteorological and ecological conditions of the plots differ considerably. Even so, the differences in the threshold figures do not vary inordinately, and it appears that they would serve the present purpose.

These threshold figures or sporidial quanta calculated for fifteen of the writer's damage-study plots vary from a low of 580 million to a maximum of 79 billion, with an average of about 12 billion. The calculations for two of the plots gave the extreme figures—from 31 billion to 79 billion—while the figures for the other thirteen plots ranged from 580 million to 26 billion. Since the *Ribes* data on the two plots yielding the extreme figures are not as reliable as those on the other plots, it seems best to eliminate these from consideration. Without them, the average figure is about 5.5 billion.

Without the two plots just mentioned, the lowest figures (580 to 1,200 million) belong to the Kelm Mt. plot (Snell, 1928, 1931a, and 1931b) and the highest (14 to 26 billion) to the McPhillips No. 2 Plot in the Pack Forest. The former, with the highest infection known to the writer in the east (96 per cent), is in a pocket in the mountains where conditions are unusually favorable for infection—frequent fogs, wet foliage at least waist high until noon or 2 P.M. daily during the summer, etc. The latter plot, with the lowest infection of all the plots studied (10 per cent) is the driest. It is an isolated stand of slowly growing pines on an open, sandy plain.

If we now compare these threshold figures with the estimated sporidium production for red currants in table 1—580 million to 26 billion, with 33 billion, respectively—we see that there may be something in the threshold of quantum idea. As the figures stand, there is no stupendous discrepancy between the number of spores necessary for the formation of a single canker over a period of thirteen years and the maximum number of sporidia on red currants. If we confine our attention only to the lowest threshold figure obtained (580 million for the 96 per cent infected Kelm Mt. plot), it is seen that the 33 billion sporidia on red currants annually would produce only 60 cankers per acre. It is not only justifiable, but quite necessary, however, to keep in mind certain facts. In the first place, the sporidium production for garden red currants given in table 1 is high, not only because the percentage of infection used (7 per cent) is higher than any found in these studies, but also because no case was met with in which even two of the six bushes in a row were infected to the maximum degree (6.6 per cent) noted for one

⁹ Snell, Walter H. Report of Investigations of Forest Tree Diseases in New York in 1940. New York Conservation Department, Albany, New York.

bush. In the second place, the sporidium production figure is high, because no account is taken of the possibly very great, if not almost complete, reduction of the sporidial output by such factors as early dropping of leaves, necrosis of spots, decreased production of telia, decreased viability of telia, etc., etc. In the third place, the threshold figures are probably minimal, because these figures are based on the *Ribes* populations extant at the time of study, after ten or fifteen years of deterioration through attack by blister rust, by other diseases and insects, through shading as the stand closed, etc. (cf. Pennington, 1922). Only moderate changes either way would bring the potential production of sporidia on red currants quite close to the minimum threshold figure, and quite likely, below an average threshold figure, not to mention the maximum figures. Further, it is evident from the discussions given here and from the data upon the Crown Point Center red currants (Snell, 1941a), that under certain conditions a very insignificant volume of sporidia would be produced—a volume of sporidia too insignificant to be of any danger to white pines at any distance from them. Indeed, it is quite possible that under extreme conditions, infected red currant bushes would produce no sporidia at all.

DISCUSSION AND CONCLUSIONS.—The study of infection of pines growing near red currants (Snell, 1941b) showed that pines are infected only rarely even at short distances from the bushes. The evidence presented in this paper shows why the foregoing situation prevails.

From the data presented upon the volume of sporidia produced, it is shown that there is a great discrepancy between the infecting powers of black currants, wild gooseberries, and red currants, even under conditions of maximum sporidium production on the red currants. Other studies of sporidial volume appear to demonstrate the actuality of a threshold or quantum phenomenon with regard to the infection of pine that can be applied to the dissemination of sporidia from all species of *Ribes*, but which has special applicability to the question of the danger of red currants to white pine. It is uncertain how the data upon production of sporidia by red currants can be translated directly into a proper distance from pine at which to eradicate these plants. The threshold or quantum principle is theoretical and the calculations based upon it lack precision. Nevertheless, in spite of the absence of an absolute conclusiveness to the evidence presented, the indication is very clear that sporidia from red currants cannot infect pine as seriously or from as great distances as those from wild gooseberries, if they can infect pine more than rarely at even very short distances, except under conditions unusually favorable for infection or under conditions in which the number of sporidia on red currants may not be greatly reduced from a theoretical maximum.

From a practical point of view, it would seem that the retention of the 900-foot eradication zone for garden red currants near pine can be justified only

upon the presentation of an abundance of sound evidence of the ability of sporidia from red currants to infect white pine at reasonable distances.

SUMMARY

From a considerable body of data upon the number of leaves, total leaf area, number of telia and number of sporidia per bush for cultivated red currants [*Ribes sativum* (Rchb.) Syme], cultivated European black currants (*R. nigrum* L.) and wild gooseberries (*R. cynosbati* L. and *R. rotundifolium* Michx.), it is shown that a garden row of red currants will produce only a fraction of the number of sporidia produced by wild gooseberries and a much smaller fraction of the number produced by black currants, even under maximum infection conditions for the red currants.

Several factors which act to reduce the total sporidium production on red currants are discussed. These are the small number of bushes in a row or patch that become infected, the high degree of resistance of mature leaves, the tendency to produce a single set of leaves a season, lowered viability of teliospores and sporidia produced, early defoliation, necrosis of blister-rust spots, and reduced size of telia.

No attempt is made to reduce the sporidium production figure for red currants to a definite distance from pine at which these plants should be eradicated, but by the use of the "threshold" or "quantum" principle, which derives a certain theoretical volume of sporidia for the production of a single canker on pine, it is demonstrated that maximum sporidium production by red currants in New York is at least very close to, if it may not be far below, the lowest limits necessary for the infection of pine, especially for serious infection, unless possibly under unusually favorable circumstances.

As with previous studies, this study definitely indicates that red currants cannot be considered very dangerous to white pine, if at all so, and that the necessity of applying the 900-foot eradication zone to them in gardens should be conclusively demonstrated.

EFFECTS OF FLUORESCEIN ON PLANT GROWTH¹

J. Sellei, Helen Sellei, A. Mayer and F. W. Went

IN RECENT years many substances have been claimed to increase the growth of plants when added to the soil or nutrient solution. Whenever such a substance is an essential building stone for the plant, not readily obtainable except by uptake through the roots, its effect is not questioned by scientists. When it is a common constituent and is synthesized by the plant itself, such as sugar or vitamin B₁, an effect can be expected only when the synthesis is not sufficient to cover the needs of the plant. In such cases a large amount of work is required to establish the exact conditions under which these substances can increase growth. Provided these conditions are established, scientists are willing also to accept the effectiveness of this second group of substances as growth-promoting.

There exists a third group of substances, which are claimed to increase growth, but which are not found normally in plants or soils. Their effectiveness cannot be deduced from theoretical considerations, unless their effect on cell or organ is already known. Scientists in general are loath to admit the effectiveness of such extraneous substances, unless very extensive experiments have been carried out. It has to be admitted that this attitude is due partly to many claims which have been based on erroneous or insufficient experiments.

To this third group belongs fluorescein, a substance not known to be present in plants normally,

¹ Received for publication March 2, 1942.

Report of work carried out with help of Work Projects Administration Official Project No. 165-1-07-172.

Particular thanks are extended to J. Greene, Thomas Barrett and Charles Newman for plant care and measurements.

but which has growth-increasing or -inhibiting properties under certain conditions. The growth-promoting effect of fluorescein has been reported over a number of years by Sellei (1934, 1935, 1936 a and b, 1940, 1941). Private communications from various investigators have seemed to cast doubt on the general effectiveness of fluorescein, as claimed in the above-mentioned papers. Other investigators, however, have observed growth increases after treatment with fluorescein, but have been "hesitant about getting connected with a field which seemed to be in very low repute among biologists." In this case the hypercritical attitude or excessive skepticism of biologists has become a hindrance to progress, since it has prevented the publication of pertinent facts.

Fluorescein has been used by many investigators to study the rate of waterflow in the xylem (e.g., Strasburger, 1891, p. 551). Such experiments were always of short duration, so that no effects on growth were observed. A very interesting use of fluorescein was made by Schumacher (1930, 1933, 1936, 1937) and others to study movements of substances in the phloem of plants. In his first experiments, in which he tried to follow with the fluorescent microscope the translocation of eosin through the conducting elements of the plant, Schumacher (1930) found that eosin specifically plugs the sieve tubes and that it stops all transport through the phloem. Fluorescein was not toxic in this respect. It seemed to have no specific effect on the plants on which it was tested, and apparently it did not prevent translocation. All experiments in which fluorescein was used to study translocation were of relatively short duration (a few days at most), and no effects of the dye on

growth were reported in that connection, nor are these experiments helpful in explaining the effect of fluorescein when plants are watered with dilute solutions.

The experiments on the photodynamic action of fluorescent dyes are of more importance for an explanation of the effect of fluorescein on growth. Boas and Merckenschläger (1925) showed that soaking of seeds in eosin causes their roots to become negatively geotropic. Similar observations were made by others; especially interesting is Boas' observation (1933) that eosin abolishes the phototropic response of *Lolium* seedlings. Boysen-Jensen (1934) observed that roots, whose geotropic sensitivity had been abolished by erythrosin, did not further produce auxin. Skoog (1935) found that indoleacetic acid in solution, stable in sunlight, is inactivated by light as soon as small amounts of eosin are added to the solution.

This photodynamic effect is similar to that found in animals, and it is a general property of the group of fluorescent dyes to which eosin belongs. For this reason fluorescein can be expected to have the same effect. Indeed, it has been found that application of strong concentrations of fluorescein to plants causes a typical stunting (Sellei, 1935), which was confirmed again in experiments carried out last summer and in others reported below. It was first believed that this effect could be attributed to the photodynamic destruction of auxin under the influence of fluorescein. This phenomenon cannot, however, explain the growth increase obtained after application of low concentrations of fluorescein.

The present paper is based on data obtained from a series of experiments made at the California Institute of Technology and at the Huntington Gardens and Library, Pasadena, and deals mainly with three problems: (1) establishment of the effects of fluorescein on growth under different soil conditions and with different plants; (2) estimation of the presence of fluorescein in the different parts of treated plants; (3) location of fluorescein effect in the plant.

Field experiments were carried out from May through November, 1941, with fluorescein applied, for the sake of convenience, in the form of 0.33 gm. Photosensin tablets. The formula of Photosensin is the following: fluorescein 5 per cent; iron sulphate 1 per cent; copper sulphate 0.1 per cent; sodium bicarbonate *ad* 100 per cent. The last ingredient hastens the dissolving of the dye and facilitates its handling. The iron added in this way is only one-quarter the concentration supplied by the nutrient solution; the copper is about equal. For this reason the controls and Photosensin treated plots did not differ essentially in their iron and copper supply. Further details of the method of application have been given by Sellei (1941).

FIELD EXPERIMENTS.—One experiment was conducted under semi-practical conditions at the Hunt-

ington gardens in San Marino.² A plot 50 x 120 feet, in light sandy loam, was laid out so that eight irrigation ditches, five feet apart, ran lengthwise through it. Tomatoes (*Lycopersicum esculentum*), corn (*Zea Mays* golden bantam), and eggplants (*Solanum melongena*), were planted along both sides of the irrigation ditches. The field was irrigated by running water through the ditches for about three hours as often as necessary. Seven times, ten to twenty days apart, fluorescein was added to the irrigation water of four ditches in the form of Photosensin tablets; the other ditches were kept as controls with pure irrigation water. The Photosensin tablets (seven to eighteen per treatment per ditch) were dissolved in six liters of water, and this solution was added dropwise to the irrigation water. Some weeks after planting, when growth seemed unsatisfactory, all rows were fertilized with Vigoro. This procedure was repeated a week later.

The experiment was not entirely satisfactory as late planting prevented full development of plants and fruit. The field proved to be inhomogeneous, for growth along the control ditches was uneven. However, an increased yield was indicated, as follows: corn yield of treated plants, an increase in weight of 21 per cent; tomatoes, an increase in fruit weight of 37 per cent; eggplant,³ an increase in fruit weight of 55 per cent. To analyze the results in greater detail a number of well-controlled plot and pot experiments were carried out.

PLOT EXPERIMENTS.—Six plots twelve by twelve feet were laid out in a rectangle, with strips of three feet separating the plots. Figure 1 shows the arrangement of the treated and control plots, which were alternating, to rule out accidental differences in yield due to systematic soil differences. The soil was heavy adobe and the plants received full sunshine. The plots were divided into four equal parts and planted, identically for all plots, with tomatoes, marigolds, beans, and beets. The plants or seeds were spaced one foot apart and were thinned as necessary. All plots were thoroughly cultivated and fertilized twice with ammonium sulphate. Treated plots received fluorescein, in the form of Photosensin tablets in solution. From May 23 until August the solution was given each ten to eighteen days, after which it was repeated every twenty to thirty days.

For the first treatment each of the treated plots received four tablets of Photosensin, with the same amount for the second treatment. Subsequent treatments consisted of five tablets of Photosensin for each of the three plots. Each tablet of 0.33 gm. was dissolved in two gallons of water. This corresponds to one part of fluorescein in 450,000 parts of water.

² The authors wish to thank the trustees of the Huntington Gardens and Library for permission to conduct this experiment, with particular thanks to Mr. W. Hertrich and Mr. M. Gschwind for their help and advice.

³ Due to frost the experiment was concluded before most of these fruits had ripened.

Fig. 1. Ground plan of the plot arrangement of the experiments of tables 1-4, showing the relative location of the plants. For marigold and tomato the net weights per plant in each plot are given in grams.

TABLE 1. Measurement of Marigold plants in plot experiment. Each figure the mean of 38 to 40 plants.

		Weight in grams per plant		Increase due to treatment	
		Treated with fluorescein	Control	Absolute	Per cent
Aug. 6	Weight of whole plant	390.7	306.3	83.8±28.7	27.3
Sept. 26	Weight of whole plant.....	363	256	107 ±34	41.8
	Weight of roots per plant.....	55.8	38.3	44.7
	Number of flowers per plant.....	26.9	19.7	36.5
	Flower surface per plant.....	520.5 cm. ²	209.5 cm. ²	148

After the treatment the plots were watered immediately until the soil was saturated. Controls received the same amount of water. The amount of fluorescein used in this experiment had been found to be optimal in experiments performed in the same type of soil in previous years (Sellei, 1940, 1941).

Experiments with Marigolds (Tagetes erecta).—Two-month-old plants of the "African Lemon" variety were set out May 23, 1941, at one-foot distance. By August 6 they had become crowded, and alternate plants were cut at ground level and weighed. Throughout their flowering period the treated plants showed a greater abundance of blooms. Flowers were cut off twice each month, so that flowering continued for a long time. A difference was apparent in the quality of treated and control blooms, the treated being larger and fuller. To obtain more objective data, actual measurements of number and diameter of flowers were taken September 4 and 18. As a more representative figure for the appearance of the flowering plants the surface instead of the diameter of the flower was calculated. Table 1 indicates that the flowers were much larger and more numerous in the treated plots, agreeing with the results of last year's experiments, as reported by Sellei (1941).

On September 26 the remaining plants were cut at ground level, roots were dug up and both were weighed individually. Table 1 gives the difference in weight between the treated and controls in percentages. It will be seen that the weight per plant was less in this second harvest than in the first, which

occurred just prior to flowering. This can be attributed to the cutting off of flowers and the dying of older leaves.

The arrangement of the marigolds in plots is shown in figure 1. It is evident that those in each of the treated plots were better than those in the adjoining control plots. However, the results varied within certain limits in the three treated plots as well as in the controls. Probably the arrangement of the plots helped to overcome existing soil differences. The difference in quality as expressed by flower surface was over 100 per cent in favor of the treated.

As a result of the statistical evaluation of plants harvested August 8 and September 26, it was found that the probability of the occurrence of the mean treated in sampling from a homogeneous untreated population was in each instance about three chances in one thousand. Considering, however, that both results were obtained from the same plots for the same plants at an earlier and a later date, the chances in the second harvest were still much less. This repetition of occurrence in one experiment considerably increases the value of the statistical results obtained.

Experiment with tomatoes (Lycopersicum esculentum).—Tomato plants of the Stone variety were set out May 23, 1941. The treatment was identical with that of the marigolds. Plants were thinned, leaving forty-four plants for treatment and forty-five for controls. All plants were staked and numbered. Ripe tomatoes were gathered from August 28, with a total of nine harvests to October 21, when the last

was made. On that date the tops of plants were cut at ground level, roots were dug up, and *all* were weighed. At all harvests the crop of each plant was collected separately and weighed individually, and the weights for each plant were totaled at the conclusion of the experiment. Tomatoes from each plant also were counted and the sugar content was determined. Leaves of the plants began to turn brown in October and the plants were in a state of deterioration when harvested October 21. Table 2 gives the pertinent data of this tomato experiment. The total crop was statistically evaluated and the difference of means was found to be:

$$\Delta = 214.8 \text{ grams} \pm 89.2 \text{ grams}$$

showing that the result of the fluorescein treatment was significant so far as the total fruit weight per plant was concerned.

The data presented in table 2 show an increase in quantity as well as an improvement of quality after the dye treatment. The treated plants had a heavier crop through the production of more and larger tomatoes than in the controls. Both treated plants and roots were heavier than the untreated ones. The quality improvement was apparent in the larger fruits with a higher sugar content. The increase was due to the sucrose percentage, which accounts for the sweeter taste of treated fruit. The root systems of the treated plants were more branched and seemed to have a much larger absorbing area.

Experiment with beans (Phaseolus vulgaris).—Black wax beans were sown May 23, 1941, three beans per hill, which were one foot apart. After germination they were thinned to one plant per hill. Flowering came soon and beans were ready for harvest July 30. Only ripe string beans were harvested; the pods which were too young were left on the stems for another harvest, August 19. The har-

vest of July 30 was statistically evaluated. August 19 all plants were removed from the ground and weighed. Data are presented in table 3.

The yield of treated plants was 534 pods, with 460 pods from controls. The weight of the average single pod from controls at the first harvest was 3.9 grams; the weight of the average single pod from treated plants of the same harvest was 4.6 grams, an increase of 17 per cent. The statistical evaluation of the yield of the same harvest showed that the difference between the treated and controls was highly significant as

$$\Delta = 7.7 \text{ grams} \pm 2.7 \text{ grams}$$

As a result of the dye treatment, beans produced a heavier crop with larger single pods, indicating an improvement of quality. The bean plants, also, were heavier in the treated plots.

Experiments with beets (Beta vulgaris rubra).—Beet seeds of Crosby's Egyptian variety were set May 24, 1941. All beets were harvested September 12, no previous harvesting or measurement having been made. For data see table 4. The statistical evaluation of the difference between the treated and control whole beet plant showed that the result of the dye treatment was significant:

$$\Delta = 36.5 \text{ grams} \pm 17.3 \text{ grams.}$$

SANDCULTURE EXPERIMENT.—In this experiment tomatoes and marigolds were grown individually in gallon cans covered inside and outside with black tar paint. Cans were 18 cm. in height and 15 cm. in diameter. In the open ground, the required space was dug up and filled with a two-inch sand and gravel layer on which the cans were placed. The space between the cans was filled with soil. The cans were filled with washed river sand.

TABLE 4. *Effect of Photosensin treatment of beet plants. Number of plants: 61 treated; 63 control.*

	Total weight in grams of all plots		Weight per plant in grams		Increase after Photosensin treatment in per cent
	Treated	Control	Treated	Control

Weight per single top.....	65.7	50.7	29.8

Each variety of plant to be tested was set in fifty cans, making ten series in which five and five received the same treatment. Series were numbered from 1 to 10, in which 1 and 10 were controls, receiving Hoagland nutrient solution only, while series 2 to 8 were treated with the same nutrient solution to which different Photosensin concentrations were added. The fifty cans were placed in the ground in two plots with consecutive numbers. The cans of series #1 (controls) were between treated pots in five different places, while all pots of control #10 were at the end of one plot.

Series 1—Control, plain nutrient solution.

Series 2—1 gm. Photosensin in 20 liters of nutrient solution or 1:400,000 fluorescein.

Series 3—1 gm. Photosensin in 30 liters of nutrient solution or 1:600,000 fluorescein.

Series 4—1 gm. Photosensin in 50 liters of nutrient solution or 1:1,000,000 fluorescein.

Series 5—1 gm. Photosensin in 100 liters of nutrient solution or 1:2,000,000 fluorescein.

Series 6—1 gm. Photosensin in 200 liters of nutrient solution or 1:4,000,000 fluorescein.

Series 7—1 gm. Photosensin in 500 liters of nutrient solution or 1:10,000,000 fluorescein.

Series 8—1 gm. Photosensin in 1,000 liters of nutrient solution or 1:20,000,000 fluorescein.

Series 9—1 gm. Photosensin in 25 liters of nutrient solution or 1:500,000 fluorescein.

Series 10—Control, plain nutrient solution.

Method of treatment.—Plants were watered daily with the designated solution. Series 2, 3, 4, 5, 6, 7 and 8 received Photosensin treatment daily; series 9, each fourteen days, only nutrient solution being given on the other thirteen days. Plants of control series were always watered first. The amount used (about 200 cc. for each can) was enough to fill cans entirely with solution and to wash out solution which was left over from the day before. The solution used dripped out of holes in the bottoms of the cans into the sand-gravel layer.

To break off roots which might have grown out of the cans, and to avoid all possible communication between the various plants, the cans were twisted once weekly. Cans were in full sunshine in warm, summer weather, although many of the mornings were heav-

ily overcast, and about four days were without any sunshine. In some of the cans two plants were placed. Approximately two weeks later, before they could have influenced each other's growth, one plant was taken out for further testing.

Plants were measured for growth response by taking their height. This part of the experiment had to be considered finished on August 20, as the plants were growing rapidly and the cans proved to be too small. Furthermore, the close planting, especially in the case of the far more developed treated ones, allowed no chance to make further vigorous growth. Plants were also weighed, and in the marigolds the flowering was noted, taking into account the time when flowering started as well as the size of treated

best growth response, had a root system 68 per cent heavier than the controls. The earlier flowering, the increased size of flowers and the heavier root system indicate the action of fluorescein.

Experiment with tomatoes (Lycopersicum esculentum).—Two-month-old plants of the Stone variety were set out in cans July 18, 1941. Treatment and arrangement of the cans was the same as in the marigold experiment. Plants of fairly equal size were selected. Differences in growth, foliage and height early became apparent. Figure 3 illustrates some of the plants on August 12. The cans were photographed as they were set in the ground, the pictures including various controls and adjoining treated plants.

TABLE 6. Weight in g. of tomato plants in sandculture experiment. Each figure is the average of five plants.

Series	1	2	3	4	5	6	7	8	9	10
Whole plant	159.3	200.4	210.5	227	207.2	188.8	237.8	229	173.2	184
Root	20.5	31.4	26.4	26.3	27.9	24	29.5	21.2	25.4	18.1

and control blooms. The accompanying photographs illustrate the difference in height and size of control plants as they were placed in the ground, comparing controls with adjoining treated plants (fig. 2, 3).

Experiment with marigolds (Tagetes erecta).—Plants one and one-half months old of the "African Orange" variety were set in cans July 18, 1941, and treated as previously described. Differences in growth, foliage and height early became apparent. Treated plants started to set flowers earlier than did the controls. Plants were tested as to blooms September 12 and 19. On September 19 the experiment was concluded. All blooms were counted, and diameter of blooms measured. Plants were taken out of cans, roots were washed, and tops and roots were weighed (see table 5).

Considering the weight of the plants, the effect of the dye was apparent mostly in the root system. The highest weights were obtained in series 9 with a mean of 33.6 grams, whereas the mean of the two control series was 19.9 grams. Averaging the results from group 5-9 on, the mean root weight was 28.1 grams, showing an increase of 41 per cent. Averaging results from all the treated series, the mean root weight was 26.1 grams, and the increase was 31 per cent.

The harvest of marigold plants showed a considerable increase in the root system of the plants after Photosensin treatment. Series 9, which showed the

As seen in table 6, the treated series had heavier roots in all of the various series, and heavier tops in most series. The mean root weight for both controls was 19.3 grams; the mean of all series treated was 26.5 grams; increase after Photosensin treatment was 37 per cent. The mean of whole plants in both control series was 171.6 grams; increase of whole plant when averaging all treated series, 22 per cent. Therefore the harvest on September 2, when the experiment was concluded, showed an increase in the weight of the treated plants, especially in their root system.

It is interesting to compare the effect of fluorescein treatment in the sandculture experiments with those of the plot experiments carried out in heavy adobe. Table 7 shows an excellent agreement between the

TABLE 7. Comparison of sandculture and soil experiments. Increase in per cent of all plants treated with fluorescein when compared with the controls.

		Sand culture	Soil experiment
Tomato	Weight of whole plant...	22%	19%
	Weight of root system...	37%	24%
Marigold	Weight of root system...	31%	44%
	Flower surface	120%	148%

two sets of results, indicating that the effect of fluorescein on growth is general and not restricted to one kind of soil.

ESTIMATION OF FLUORESCHEIN IN TREATED PLANTS.

—The foregoing experiments establish the growth-promoting effect of fluorescein when used in low concentrations to water plants. The following determinations were carried out to determine in which manner this effect could be brought about.

In the *Avena* test there is no trace of growth-promoting effect of fluorescein. When agar blocks containing 1:1,000 to 1:100,000,000 fluorescein are placed unilaterally on the cut surface of decapitated coleoptiles, the plants remain perfectly straight. Nevertheless, the dye has penetrated the coleoptile cells. No toxic effects were noticed after twenty-four hours even in the highest concentrations. This shows that fluorescein does not have an auxin-like growth-promoting effect.

A number of determinations of the fluorescein content were made to find its distribution in the treated plant. To this end the plants were extracted both fresh and dried. The material was boiled for a short time with very dilute NaOH or NH_4OH . Small amounts of a fluorescent material were thus extracted from plants treated with 1:400,000 fluorescein, but these amounts were of the same order of magnitude as found in extracts from control plants.

After this negative result the bleeding exudate of tomatoes was collected and investigated as to fluorescein content. The control plants gave practically no fluorescence in their exudate. When the tomatoes had been watered with concentrations ranging from 1:400,000 to 1:2,000,000 fluorescein one to four days previous to collecting the exudate, no increased fluorescence of the exudate was observed. Since the method of determination is sensitive down to a concentration of 1:20,000,000, it follows that the fluorescein is excluded from the xylem during the water uptake by its roots, since the external concentrations were at least ten to fifty times higher than those in the xylem.

The two last mentioned facts make it rather certain that most of the applied fluorescein does not reach the top of the plant. If it were taken up, we have to assume that either its fluorescence is covered, which does not seem very likely, or that the fluorescein is chemically changed so as to give no fluorescence.

The determinations of the fluorescein content of treated roots bear out the above conclusions. Whereas the color of the control root systems was white, the roots of plants treated with 1:400,000 fluorescein were rust-colored, grading down to light yellow in the lower concentrations. These roots were washed free from the adhering sand and were dried and extracted with cold water. The extract was strongly fluorescent. It is difficult to give exact data, since the first washing of the roots may already have removed a considerable amount of absorbed dye, but the determinations show that the fluorescein on the roots was at least five times more concentrated than in the

solution with which the plants were treated. This confirms the earlier conclusion that the root system excludes the applied fluorescein from the above-ground portion of the plant.

When much higher concentrations of fluorescein are applied to the plants by watering them with a 0.3 per cent fluorescein solution, then a marked dwarfing of all parts of the plant results. In those plants, however, fluorescein moves upward in the shoot, which in some cases becomes clearly stained, and sometimes fluorescein is found in the bleeding exudate of such plants.

However, when a 0.2 or 0.1 per cent fluorescein solution is applied, less dye is found in the above-ground parts. Only when the root system is injured do large amounts of fluorescein move up into the top of the plant, which consequently dies. But as long as the root system remains healthy, the top of the plant remains alive also, even in these high concentrations of fluorescein. Only the dead root cells become stained. Small amounts of fluorescein move up in the xylem and are absorbed on the vessel walls, so that in the top of the plant only very small amounts of fluorescein can be detected by extraction. In three cases, in which tops or leaves of plants watered with a 0.1 per cent solution of fluorescein were extracted three days after treatment, less than 0.0001 per cent was detected. Only in one killed plant was a concentration between 0.01 and 0.1 per cent found. In the bleeding exudate of the plants receiving 0.1 and 0.01 per cent and weaker solutions of fluorescein, no trace was detected. Thus, we must conclude that a sort of negative accumulation of fluorescein occurs in the roots.

Greenhouse experiments on the immediate effect of fluorescein on growth.—To study in greater detail the way in which fluorescein exerts its growth-promoting and growth-inhibiting effect, the following experiments were carried out with tomato plants. In an attempt to ascertain whether we were dealing with a photodynamic effect, the growth of tomato plants in darkness was compared with their growth in light, both with and without fluorescein. Since growth of tomatoes stops in darkness within twenty-four hours, due to a lack of sugar, plants in darkness and in light can be made comparable by treating both groups with a 10 per cent sucrose solution. Under such a treatment growth in darkness continues at essentially the normal rate for many days, and the groups growing in light and in darkness have comparable growth rates.

For the following experiments small tomato plants, grown in sand in four-inch pots and watered with complete Hoagland nutrient solution, were divided into two groups. One group was taken from a greenhouse into a darkroom, kept at 27°C . and ± 70 per cent humidity. The other group was moved into an air-conditioned greenhouse maintained at 26.5°C . and 70 per cent humidity. The only difference between the two groups of plants was that during ten hours each day the tomatoes in the greenhouse were exposed to diffuse daylight. All leaves were cut off the

TABLE 8. *Elongation in mm. of main stem and young leaf (10 to 15 mm. long) of tomato plants in the three-day period following watering with fluorescein solutions. Only two full-grown leaves left per plant, immersed in 10 per cent sucrose solution (exp. 1, 2), or left free in air (exp. 3). Each figure mean of six to eight plants. Temperature 27°C.; 70 per cent humidity.*

Concentration of fluorescein	Experiment 1				Experiment 2				Experiment 3

plants except the two youngest full-grown leaves and the leaf primordia less than fifteen mm. long. In most of the experiments the two leaves left on the plants were immersed in glass vials filled with a 10 per cent sucrose solution, so that they could take up the sugar by diffusion through their leaf surface. Part of the plants were watered with tap water and part with different concentrations of Merck fluorescein solutions. Every twenty-four hours the length of the stem and of the largest leaf primordium was measured. The growth of the young leaves in darkness fell off rapidly, so that their growth stopped after two or three days, but stem elongation both in darkness and light, and leaf growth in light, continued for more than four days. After this time the leaves in the sugar solution were mostly injured, so that the conclusions based on longer periods of observation became unreliable.

From table 8 it appears that growth in length of stem in darkness is equal to, or exceeds, that in light, provided sucrose is supplied to the plants. The effect of fluorescein in high concentration is to reduce growth in length 60 to 90 per cent, both in light and in darkness. Consequently, the growth inhibition is not due to a photodynamic effect of the fluorescein, as might have been expected from Skoog's observation (1935) that eosin is a photosensitizer for auxin destruction. The effect of high concentration of fluorescein on leaf growth is much less pronounced, and amounts to 30 per cent growth decrease at most. In another experiment it was found that at 1:2,000 fluorescein there was the same inhibition of stem growth as in the higher concentrations, but no decrease at all in leaf growth. In experiment 2 of table 8 a slight increase in stem growth is observed in the lower fluorescein concentrations. In experiment 3 this effect is more pronounced. Thus, it seems possible to duplicate the growth-promoting effects observed in field experiments in greenhouse experiments of short duration.

DISCUSSION.—The experiments reported in this paper confirm the results of earlier experiments in which fluorescein was found to increase growth when applied in low concentrations and inhibit growth in high concentrations. The growth increase was observed in different plants and under different soil

conditions. The experiments with sand cultures are of special importance, since they show that it is the actual concentration of the fluorescein which is effective. There was little, if any, adsorption of the dye to the sand, which was washed clean every day with a fresh nutrient solution containing fluorescein. Most of the dye was found adsorbed on the root system; actual fluorescein determinations showed that the highest concentration was found around the root system, whereas little or nothing moved up in the shoot of the plant. We have, therefore, to look for the primary effect of the fluorescein in the roots of the plant, since only there are measurable amounts found. This is substantiated by the greenhouse and darkroom experiments. The immediate effect of the applied dye was on stem growth and not on leaf growth, and the effect was the same in darkness as in light. Leaf growth is regulated by growth factors formed in the older leaves and transported towards the young growing leaves (Bonner and Haagen-Smit, 1939). When no fluorescein moves up in the shoot, no direct effects on leaf growth could be expected. Stem growth, on the other hand, is regulated by auxin and caulocaline (Went, 1938). Since the effect is the same in light as in darkness, and fluorescent dyes are known to act as photosensitizers in auxin destruction by light (Skoog, 1935), it is not likely that the effect of fluorescein is on the auxin. Caulocaline, on the other hand, is formed in the roots, and, therefore, could be affected by fluorescein in contact with the root system. Also, no effect of light would be expected if the dye should affect caulocaline production in the roots.

Although no conclusive experiments have been performed, proving beyond doubt the way in which fluorescein increases or decreases growth, all observations are consistent with the assumption that it acts by way of the root system. Since we know that all parts of a plant are interconnected by means of hormones or food correlations, effects on one part of the plant will have systemic effects in experiments of longer duration. In most of the experiments described in this paper the growth increase due to fluorescein was relatively greater in the root system than in the tops, indicating that the effect on the root sys-

tem was the primary and the effect on the top a secondary effect of fluorescein.

The plot experiments in soil were carried out in the heavy adobe of the same type as used in previous years (Sellei, 1940, 1941), so that without preliminary trials the optimal concentration of fluorescein could be applied. This concentration was slightly lower than the one used in earlier experiments in Hungary and may vary from soil to soil. For this reason it is interesting that in washed sand the same effect of fluorescein can be obtained. This makes it possible to carry out comparable experiments in many different localities. It should be pointed out that a repetition of the sand-culture experiment in late fall, when the temperature was much lower and growth of tomatoes was very slow, gave smaller growth increases with the same concentrations of fluorescein which had given good results in the summer months. This is in accord with the general experience, that fluorescein treatment is much more effective during midsummer than at other times of the year. To judge from experience, this seems to be due to the higher temperature and better growing conditions in summer. It should be emphasized that, if our assumption is true, the primary effect of fluorescein is on the hormone production of roots, increased growth can be expected only when all other growth factors—mineral nutrition, assimilation, auxin, etc.—are optimal or at least not limiting growth.

The growth effects of dyes are not limited to those

of the fluorescein group. This observation was made by Sellei in earlier papers (1934, 1935), and more recently by Patterson (1941, 1942), who published data concerning the effect of neutral red on cell division in roots.

SUMMARY

The experiments reported confirm the results of earlier experiments in which fluorescein was found to increase growth of plants when applied in low concentration and to inhibit growth when applied in high concentration.

Plants treated with low concentrations responded by producing heavier tops, roots, more fruit and also by showing a qualitative improvement.

Experiments in sand culture showed practically the same per cent increase as those carried out in plots in heavy adobe, indicating that the effect of fluorescein is general and not restricted to one kind of soil.

Sand culture experiments of short duration in the greenhouse and the darkroom, when giving to young tomato plants fluorescein of high and low concentration, showed that a definite acceleration or inhibition of stem elongation was evident within three days.

A possible explanation is discussed of the mechanism of the action of fluorescein.

ANATOMICAL AND TAXONOMIC APPROACHES TO SUBGENERIC SEGREGATION IN AMERICAN QUERCUS¹

A. H. Tillson and C. H. Muller

BEFORE THE turn of the century it was not uncommon for a taxonomist to take as his primary objective the discovery of relationships within large categories of plants and to use as his principal tool the anatomy of the groups on the assumption that it could be utilized as a key to phylogeny. Most recent taxonomic studies have tended to concern themselves with relationships among lesser taxonomic entities which scarcely demand an anatomical approach.

The purpose of this paper is to bring together the several treatments of subgeneric groups in American *Quercus* which have been based variously on floral morphology and on wood anatomy, to present additional data particularly on the wood anatomy, and to evaluate the several types of data for purposes of establishing the boundary lines between the various groups. The age-old human failing of regarding one's special line of interest as the most important evidence is met here freely. Most workers have conscientiously weighed all the evidence available to them and have rendered unbiased conclusions. Even they, however, often seem not to have realized that the characters they so unconditionally described should in most cases have been preceded by the word "usually." Trelease (1924) is outstanding among them in his readiness to point out exceptions.

Oersted (1871) applied floral and fruiting characters in the genus *Quercus* to effect segregation of the species into subgenera. His subgenus *Erythrobalanus* is characterized by elongate styles with spatulate stigmas, acorn shells tomentose within, and abortive ovules apical. The subgenus *Lepidobalanus* is distinguished by short styles with broad abruptly dilated stigmas, acorn shells glabrous within, and abortive ovules basal. Subsequent observations have added lesser differences between these groups. Oersted's subgenus *Macrobalanus* includes a group of large-fruited species which differ from *Lepidobalanus* in their unequal cotyledons and lateral radicles.

The leaves of *Erythrobalanus*, if at all toothed, lobed, or acute at the apex, have the teeth or lobes and the apex aristate-tipped by an extension of the veins. Those of *Lepidobalanus* fall into two classes. In one the lobing is broadly rounded and lacks any tips; in the other, if the leaves are toothed, the teeth are tipped by short mucronate projections which are very thick with much sclerenchymatous tissue. In no case are the leaves of *Lepidobalanus* aristate-tipped, but in *Q. dumosa* and *Q. turbinella* the mucronate tips may be quite elongate so as to simulate aristae of *Erythrobalanus* to a certain extent. The cup scales of *Erythrobalanus* are characteristically thin, while those of *Lepidobalanus* are corky-thickened basally. The bark of *Erythrobalanus* is hard, smooth, or furrowed (but scarcely scaly) and dark brown or black. In *Lepidobalanus* it is rather soft

and corky, scaly or flaky, and gray or glaucous. In a few species of *Lepidobalanus*, e.g., the series *Virentes*, the bark simulates that of *Erythrobalanus*.

Schwarz (1936) has elevated *Erythrobalanus* and *Macrobalanus* to generic rank on the basis of these same characters. He retains *Lepidobalanus* as a subgenus of *Quercus*, but he proposes *Sclerophyllodrys* as a new subgenus to include, among other groups, what he calls the section *Protobalanus* Trelease, apparently without regard for the fact that Trelease's name was published as a subgenus (Trelease, 1924) and, therefore, antedates Schwarz' name. Trelease, on the other hand, maintains Engelmänn's subgeneric name, *Leucobalanus* (Engelmänn, 1876), even though it is clearly synonymous with *Lepidobalanus* (*sensu* Oersted). Most American writers to date have followed Trelease in his adoption of *Leucobalanus*. Camus (1938) has set up the subgenus *Euquercus* in the sense in which the name *Lepidobalanus* was first used by Endlicher (1847), namely, to designate all those species of *Quercus* exclusive of certain Asiatic species with cup scales fused into rings. Bailey (1910) proposed the subgenus *Biotobalanus* to include the live oaks, a very unnatural group of evergreen species belonging to both *Erythrobalanus* and *Lepidobalanus*. He based this segregation solely on characters of wood anatomy.

The subgeneric names of American oaks, then, are *Leucobalanus*, *Sclerophyllodrys*, and *Euquercus* (which are superfluous names), *Biotobalanus* and *Macrobalanus* (which are scarcely worthy of subgeneric distinction), and *Lepidobalanus*, *Protobalanus*, and *Erythrobalanus*. The question as to whether any or all of these deserve generic rank is not within the province of this paper, but the evidence would seem clearly to prohibit any such splitting (Muller, 1942).

REVIEW OF ANATOMICAL LITERATURE.—Although oak wood was one of the earliest subjects of anatomical investigation (Malpighi, Grew, Leeuwenhoek, and others), Abromeit (1884) was the first to make extensive use of anatomical characters to show relationships within the genus *Quercus*. Investigating the structure of fifty-five species of European, Asiatic, and American oaks, he separated them, on the basis of the arrangement of the vessels and fibers and the thickness of the vessel walls, into groups corresponding in general to the then accepted taxonomic views. The black or red oaks, *Erythrobalanus*, were found to have the walls of the small summerwood vessels, and frequently also the walls of the large springwood vessels, six to eight microns thick, with round or elliptical lumina. The white oaks, *Leucobalanus* (*Lepidobalanus*), exhibited two anatomical types. The live oak type had thick-walled summerwood vessels, while the vessels of the other white oaks had thin walls only four microns thick and "not

¹ Received for publication March 3, 1942.

Fig. 1-9.—Fig. 1. *Quercus falcata*. Transverse section showing ring-porous wood with thick-walled, rounded summer-wood pores. $\times 180$.—Fig. 2. *Q. agrifolia*. Transverse section showing diffuse-porous wood with thick-walled, rounded

round." Only one exception was observed, *Q. Wislizeni*, a species in *Erythrobalanus* with thin-walled vessels.

Bailey (1910) examining forty-five species of American oaks, found that in *Lepidobalanus* the summerwood vessels are numerous, small, thin-walled, and angular, while in *Erythrobalanus* they are more scattered, larger, thick-walled, and circular. Tyloses are rare in the summer vessels of the red oaks, but frequent in the thin-walled vessels of the white oaks. In the live oaks, for which he suggested a new subgenus, *Biotobalanus*, the summerwood vessels are similar to those of the red oaks. They differ from the latter, however, in that the live oaks have aggregate rays, are diffuse-rather than ring-porous, and usually have no tyloses in the vessels. These so-called aggregate rays, at first considered to have arisen by a phylogenetic process of compounding, were shown by further investigation (Bailey & Sinoth, 1914; Barghoorn, 1940, 1941; Bailey and Howard, 1941) to have resulted from the disintegration or dissection of wide multiseriate rays.

Sudworth and Mell (1911) describe the woods of some thirty American oak species, classifying them according to the differences in the form and arrangement of the large and small vessels, wood fibers, and wood-parenchyma fibers. Although they do not make use of the thickness of the walls of the summerwood pores in their key, this character is mentioned in the descriptions of species or shown in the drawings.

Williams (1939) again made use of the difference in outline and thickness of the walls of the summerwood pores to delimit some fifty species of *Erythrobalanus* and *Leucobalanus*. Because of the contradictory nature of the accepted criteria, he proposed that the two groups be redefined.

"*Leucobalanus*: Summerwood pores angled, thin-walled [less than 3 microns]; leaves devoid of spinose teeth or bristle-tipped lobes."

"*Erythrobalanus*: Summerwood pores rounded, thick-walled [3 to 8 microns]; leaves wholly or in part with bristle-tipped lobes, apex apiculate, or margins with spiny teeth."

Eight species of white oaks were found to exhibit the "red oak" type of wood. Since he also considered their leaves to have bristle-tipped lobes or spiny teeth on the margins, he suggested the transfer from *Leucobalanus* to *Erythrobalanus* of the following eight species: *Q. Emoryi*, *Q. dumosa*, *Q. virginiana*, *Q. reticulata*, *Q. arizonica*, *Q. oblongifolia*, *Q. Engelmanni*, and *Q. Douglasii*.

In a more recent paper Williams (1942a) describes in detail the types of tyloses found in oak vessels and confirms the observation that tyloses are in

general more abundant in the white oaks than in the black oaks. In a third paper (1942b) he reemphasizes his earlier claim for the significance of late summerwood vessels as a means of distinguishing the subgenera of *Quercus*. Additional wood characters which are variously more or less loosely correlated with the vessel characters are discussed and the errors in Abromeit's pioneer effort are pointed out.

MATERIALS AND METHODS.—The stems used in this study were obtained mostly from herbarium specimens, although a few were obtained from trees growing in the vicinity of Washington, D. C. In table 1 is given a list of the 104 species examined, together with the name of the collector and collection number, or, if there was no number assigned, the date of collection.

All of the stems studied were at least three years old and from mature trees. In several species wood samples were taken from various parts of the same tree in order to observe the effect of age and exposure on the anatomy of the wood. Small blocks of stem were placed in the chuck of a sliding microtome and a jet of stem was played upon the block as the sections were being cut. Transverse and longitudinal sections were cut 22 microns thick and stained with safranin and fast green. Photographs were made, using XI and A filters, at a magnification of about 180 \times .

RESULTS.—Transverse sections of the stem show wide vascular rays radiating outward with much narrower uniseriate or biseriate rays between them. The wide multiseriate rays appear in tangential section as more or less homogeneous masses of round cells, as shown in *Q. grisea* (fig. 9). Occasionally the large rays appear to be broken up into aggregates of narrower rays by fibers and wood parenchyma which traverse them in a diagonally vertical direction, as in *Q. diversicolor* (fig. 8). These so-called aggregate rays are found both in *Lepidobalanus* (*Q. arizonica*, *Q. cordifolia*, *Q. diversicolor*) and in *Erythrobalanus* (*Q. durifolia*, *Q. palustris*). Intermediate stages, as evidenced by the frequent included fibers and wood parenchyma, are widespread in the genus.

The annual rings present a range from ring-porous to diffuse-porous. *Quercus falcata* (fig. 1), *Q. alba* (fig. 6), and *Q. Brayii* (fig. 7) illustrate the ring-porous type, with an abrupt decrease in size from the large springwood vessels to the much smaller summerwood vessels. The diffuse-porous condition appears in *Q. chrysolepis* (fig. 3) and *Q. grisea* (fig. 4), where large vessels are present throughout the year's growth. This variation appears related to a great extent to the climate and the length of the growing season. The deciduous oaks, such as

summerwood pores. $\times 180$.—Fig. 3. *Q. chrysolepis*. Transverse section showing diffuse-porous wood with thick-walled, rounded summerwood vessels. $\times 180$.—Fig. 4. *Q. grisea*. Transverse section showing diffuse-porous wood with thick-walled, rounded summerwood vessels. $\times 180$.—Fig. 5. *Q. arizonica*. Transverse section showing semi-ring-porous wood with thick-walled, rounded summerwood vessels. $\times 180$.—Fig. 6. *Q. alba*. Transverse section showing ring-porous wood with thin-walled, angular summerwood vessels. $\times 180$.—Fig. 7. *Q. Brayii*. Transverse section showing ring-porous wood with thin-walled, angular summerwood pores. $\times 180$.—Fig. 8. *Q. diversicolor*. Tangential section showing "aggregate" ray and uniseriate rays. $\times 180$.—Fig. 9. *Q. grisea*. Tangential section showing wide multiseriate ray and uniseriate rays. $\times 180$.

Q. stellata, *Q. alba*, *Q. falcata*, and *Q. coccinea*, are predominantly ring-porous, while the evergreen or partially evergreen oaks, as *Q. virginiana*, *Q. agrifolia*, *Q. grisea*, and *Q. arizonica*, tend to be semi-ring-porous to diffuse-porous.

In *Erythrobalanus*, although the springwood vessels of different species may have either thick walls or thin walls, the summerwood vessels are always

thick-walled, more or less scattered, and circular in outline, as shown in *Q. falcata* (fig. 1) and *Q. agrifolia* (fig. 2). Contrary to the statement of Abromeit (1884), *Q. Wislizeni* is no exception, but exhibits the typical red oak vessels.

In *Lepidobalanus* two types of summerwood pores occur. In thirty-one of the sixty species of white oaks examined, including *Q. grisea* (fig. 4) and *Q. ari-*

zonica (fig. 5), the vessels are similar to those of the red oaks. The leaves of many of these species are thick and hard, and tend to be evergreen, while others are clearly deciduous. Mucronate tips, cusps, or "pseudo-bristles" are developed frequently in almost all of those white oaks having thick-walled, rounded summerwood pores. In the remaining twenty-nine white oak species the later-formed vessels are much smaller and more numerous, thin-walled and angular in outline, as illustrated by *Q. alba* (fig. 6) and *Q. Brayi* (fig. 7). In specimens taken from about the thirtieth annual ring of several red and white oak species the summerwood pores were larger than those in the much younger herbarium specimens, but the characteristic differences in shape and wall thickness noted above were still evident. On leaves of some of these species with thin-walled, angular summerwood pores, mucronate tips are entirely lacking, while in a few others there is a tendency toward the development of mucronate tips. Furthermore, the leaves of this group are distinctly deciduous. Tyloses, often abundant in these species, are also found in many other oak species, although not always in such large numbers. *Quercus chrysolepis* (fig. 3) and *Q. tomentella* of the intermediate subgenus *Protobalanus* have typical red oak summerwood vessels. In table 1 are listed the oak species examined, together with the type of wood and leaf margin found in each.

SUBGENERA AND SECTIONS OF AMERICAN QUERCUS.—The three subgenera recognized by Trelease (1924) are supported by the evidence of both wood anatomy and the conventional taxonomic characters. *Erythrobalanus* is set off from *Lepidobalanus* by its constantly tomentose inner surface of the acorn shell. This is fairly well correlated with the differences usually apparent in the bark, leaves, flowers, cup scales, and position of abortive ovules. Although any of these correlated characters may be lacking in one or another species, no instance is known of more than one character failing to appear in a single species.

The subgenus *Protobalanus* occupies a more or less intermediate position between the first two. It has the tomentose acorn shell and biennial fruition of *Erythrobalanus*, the short broad stigmas of *Lepidobalanus*, and characteristically lateral abortive ovules more or less like certain species of both groups.

Although the characters which set off the subgenera are, from species to species, not very constant, they are found in a great preponderance of the species. The study of wood anatomy was undertaken with the definite hope of finding contributing evidence by means of which to clarify the subgeneric lines, but no such evidence has been found. Williams' transfer of *Lepidobalanus* species with thick-walled, rounded summerwood vessels to *Erythrobalanus* is not supported by the examination of a larger number of species. The nature of the vessels in the late summerwood has been demonstrated not to distinguish the subgenera from one another but rather to separate one subgenus approximately into halves.

In *Lepidobalanus* about 50 per cent of the species studied have summerwood vessels which are thick-walled and rounded like those of *Erythrobalanus* and *Protobalanus*. These *Lepidobalanus* species characteristically have leaves with mucronately tipped teeth. The remainder of the subgenus is characterized by summerwood vessels which are thin-walled and angular in outline and by leaves with a tendency toward broadly rounded teeth or lobes (but many species more or less constantly develop mucronate tips). The round-lobed and thin-walled group belongs in the section *Robur* of Spach (1842), and the sectional name *Prinopsis* Schwarz (1936) has been applied to some of the mucronate-tipped and thick-walled species. It seems that there is no clear distinction between these two types.

The following diagnostic key presents the subgenera as they are now understood.

Acorn shell glabrous within, cup scales keeled or corky-thickened basally, abortive ovules basal or rarely lateral, styles short, stigmas broad and abruptly dilated, leaves, if toothed or lobed, with broadly rounded teeth or lobes or merely mucronate tips, not aristate-tipped by projection of the veins.

Subgen. *Lepidobalanus* Oersted

Cotyledons unequal, the radicles therefore lateral and obliquely directed (all tropical American species)

Sect. *Macrobalanus* (Oersted)²

Cotyledons equal, the radicles therefore apical and apically directed.

Sect. *Robur* Spach³

Acorn shell densely tomentose within, abortive ovules apical or lateral, very rarely basal.

Cup scales somewhat thickened basally and conspicuously tomentose, abortive ovules lateral, styles short, stigmas abruptly dilated, leaves, if toothed, with spinose or rarely aristate tips. Subgen. *Protobalanus* Trelease.

Cup scales flat or very rarely thickened basally, inconspicuously pubescent or glabrate, abortive ovules apical or rarely lateral or even basal, styles elongate and very gradually dilated to form the stigmas, leaves, if toothed, with aristate tips formed by the projection of the veins.

Subgen. *Erythrobalanus* (Spach) Oersted

SUMMARY

The wood anatomy of 104 species of American *Quercus* has been examined and the anatomical characters compared with the conventional taxonomic characters in an effort to establish a correlation between the two types of data. The well known character of red oak (*Erythrobalanus*) wood in which the summerwood vessels appear rounded in cross section and have thick walls (greater than three microns) was found to occur without exception in the red oaks. The white oaks (*Lepidobalanus*) have been regarded as characterized by summerwood vessels with thin walls (less than three microns) and angular in outline. Exceptions to this were considered by Williams as belonging to *Erythrobalanus*. About 50 per cent of the *Lepidobalanus* species examined in the pres-

² Subgenus *Macrobalanus* Oersted, treated as the genus *Macrobalanus* by Schwarz.

³ Includes section *Prinopsis* Schwarz.

ent study exhibited red oak wood characters. These characters are correlated very poorly with evergreen habit and the presence of mucronate tips on the leaves; they are not at all correlated with the conventional taxonomic characters of the subgenera. The anatomical characters of the wood, therefore, do not constitute a basis for subgeneric division and

only roughly indicate a possible division of the white oak subgenus into sections.

THE DISTRIBUTION OF AUXINS IN BULBS OF LILIUM LONGIFLORUM¹

William S. Stewart and Neil W. Stuart

WHILE AUXINS are known to occur in seeds and certain other storage organs (Went and Thimann, 1937), no previous tests of lily bulbs for these substances appear to have been made. Easter lily (*Lilium longiflorum* Thunb.) bulbs are always subjected to a period of cool storage at about 35°F. prior to forcing for flower production. This practice is followed primarily to maintain the bulbs in good condition for successive plantings throughout the year, but it is also known to exert a marked effect in accelerating flowering. Under the most favorable conditions flowers are produced from cool-stored bulbs in about one-third the time required for flower production from bulbs not cool-stored. This acceleration in flowering is accompanied by longer internodes and fewer leaves, suggesting that changes in the growth-regulating substances may be involved. Before undertaking a study of the possible role of auxins in accelerating flowering of cool-stored bulbs of Easter lilies, these preliminary studies were made: first, on the distribution of auxins in various parts of

the bulb; and second, on the changes in this distribution associated with the initiation of growth.

MATERIALS AND METHODS.—The Easter lily bulbs used in the experiments reported here were of the Creole variety grown in Louisiana in 1940, and forced in the greenhouses at the United States Horticultural Station, Beltsville, Maryland, during the winter and spring of 1940-1941. The forced bulbs were allowed to remain in the greenhouses until fully ripened. Late in July the bulbs were harvested, graded, packed in moist peat moss and stored in a cellar where the temperature ranged from 70° to 85°F. On November 13 duplicate samples of the dormant bulbs 12 to 14 cm. in circumference were dissected and their relative auxin content determined. Each bulb was dissected into five portions (fig. 1) as follows: (1) the outer scales removed until the remaining portion of the bulb was 8 cm. in circumference; (2) the inner scales, or remaining scales down to the growing point; (3) the basal plate of the bulb on which the scales are borne; (4) the stem which for part of its length is surrounded by the basal plate;

¹ Received for publication March 4, 1942.

and (5) the stem tip, or the apical 3 mm. of the stem. Upon dissection, the respective parts from fifteen bulbs were combined, weighed, and put directly into ether. The outer scales were extracted with 450 cc. of ether, the inner scales with 300 cc., the basal plate 150 cc., the stem 50 cc., and the growing point 50 cc. In the stem tip and stem the ratio of tissue surface to

Fig. 1. Longitudinal section of a bulb of *Lilium longiflorum* showing regions sampled separately for study of auxin content. S.T., stem tip; S., stem; B.P., basal plate; I.S., inner scales; O.S., outer scales.

tissue volume is greater than in the other parts of the bulb. The effect of these differences on auxin extraction is not known.

Although auxin extraction methods are not yet perfected, it is generally agreed that by the use of an arbitrary but uniform extraction method, amounts of auxin in various tissues may be compared. However, absolute amounts cannot be determined, for as yet exhaustive extraction methods for auxin are not known for every plant tissue. In these experiments peroxide-free ethyl ether was used to extract the auxin (van Overbeek, 1938a). The whole tissues were extracted overnight in this solvent. The ether was then decanted and evaporated to dryness in a shell vial. The residue containing auxin was taken up in a small volume of 1.5 per cent melted agar and molded into blocks for auxin determination by the standard *Avena* test. Any waxes or other solids deposited in the vial on evaporation of the ether were melted and shaken into the agar by placing the vial in a rapidly boiling water bath for a very short time. Continuous records of *Avena* coleoptile curvature with time, even when the curvatures were caused by extracts of the highest auxin concentration, showed no "cross transport" or inhibition due to high concen-

tration. As the amounts of extracted auxin were considerably less than those needed to cause a maximum angle of curvature of *Avena* coleoptiles, auxin determinations of dilutions of the original extract were not made.

The first experiments showed that only the growing point and stem yielded sufficient amounts of auxin to cause definite *Avena* coleoptile curvatures. The kymograph technique was used to measure the smaller amounts of auxin in the other tissues (Schneider and Went, 1938). By inserting a 0.12 mm. diameter silver wire into the primary leaf, curvatures of the coleoptile of less than one degree become magnified and are readily and accurately measurable, since the tip of the coleoptile is in effect extended about 6 cm. Furthermore, interference of regular auxin curvatures by growth inhibitors extracted along with the auxin are made apparent by automatic recording of the changing curvatures of the coleoptile every four minutes over a period of 280 minutes rather than just at the end of 90 minutes as in the standard *Avena*

Fig. 2. Response of *Avena* coleoptiles with time, to growth regulators extracted from the inner scales of *Lilium longiflorum* on Nov. 17. Ordinates indicate micrograms of indoleacetic acid equivalents per kilogram fresh weight. Above the horizontal axis, the positive values indicate growth stimulation or auxin predominance; below this axis, the negative values indicate growth inhibition. Abscissas indicate time in hours. Each determined point represents the average of twelve coleoptiles.

test. Although such an inhibiting substance was extracted from the outer and inner scales and from the basal plate, this substance did not manifest itself at the 90-minute interval when the auxin curvatures were measured (fig. 2). After this time it caused a growth inhibition of the coleoptile, often resulting in strong "positive" curvatures, and in a marked plas-

TABLE 1. *Auxin distribution in bulbs of Lilium longiflorum on November 13.*

^a A and B indicate separate samples.

molysis and collapse of the coleoptile cells under the agar block. Apparently the substance caused the inhibition by killing the coleoptile cells. In this respect it is quite different from a substance obtained from radish (*Raphanus sativus* L.) which causes coleoptile growth inhibition in less than 90 minutes without the plasmolysis and collapse of the coleoptile cells (Stewart, 1939). Units of auxin in the various parts of the bulb are expressed arbitrarily as micrograms of indoleacetic acid equivalents per kilogram of fresh weight of tissue.

RESULTS AND DISCUSSION.—Extractions made on November 13 showed that the stem tip contained about one thousand times the concentration of auxin present in the scales and basal plate. The stem contained one-fifth the amount of auxin in the stem tip and two hundred times the concentration present in the scales and basal plate (table 1). The full significance of the high concentration of auxin in the meristems is of course unknown. Indoleacetic acid at a concentration of 100 milligrams per liter when applied to seedling bean stems induces a mobilization of food material toward the place of application (Mitchell and Stuart, 1939). It seems possible then that the relatively high concentration of auxin in the stem tip may have a similar function and mobilize food material toward the growing region.

The differences in auxin content of the various portions of the dormant lily bulbs made it desirable to investigate how this distribution might change as the bulbs resume active growth. Accordingly, 200 bulbs were packed in moist peat moss on November 13 and stored at a constant temperature of 77°F. These bulbs were from the same lot used for the determinations just described. From previous experience (Brierley, 1941) it was known that bulbs maintained at summer temperatures for some months would start active growth as soon as they were provided with moisture.

At five intervals between November 13 and December 15, duplicate random samples of fifteen bulbs each were withdrawn from storage, dissected, and their auxin concentration determined. The results are summarized graphically in figures 3 and 4. Auxin

concentration in the stem tip on November 6 is also given; the auxin concentration in the other tissues on this date were not obtained. The data show that during the storage there was a continual decrease in

Fig. 3. Auxin, as micrograms of indoleacetic acid equivalents per kilogram fresh weight, extracted from stem tip and stem of bulbs of *Lilium longiflorum*. Bulbs kept at 77°F.

auxin in the outer and inner scales and in the stem. In the basal plate and growing point there was an initial decrease followed by a definite increase (figs. 3 and 4). In the growing point the auxin content had increased about a third. The significance of these changes is again a matter for conjecture. It has been reported that actively elongating stem tissues exhibit a lower auxin concentration than do their apical meristems (van Overbeek, 1938b). This relationship

appears to exist in lily bulbs. Simultaneously with the beginning of accelerated growth, the ratio of auxin in the apical meristem to that in the stem increased about fourfold. This was due to increase of auxin in the growing point as well as to its decrease in the stem. On December 15 the concentration of

(2) stem axis, 5.20; (3) basal plate, 0.08; (4) inner scales, 0.03; (5) outer scales, 0.02.

During the storage period the bulbs produced new roots, and the stem elongated about two centimeters. It is noteworthy that the increase in auxin occurred in the regions of meristematic activity, *i.e.*, in the basal plate where there are numerous root primordia and in the growing point. The auxin relations in the lily bulb are somewhat comparable with those in dormant vegetative buds where an increase in auxin has been found to precede the initiation of accelerated growth (van Overbeek, 1938b). In bulbs the increased auxin in the basal plate and in the apical meristem might stimulate the formation of new roots and promote accelerated stem growth. Studies of auxin distribution in freshly harvested, cool-stored bulbs are now in progress.

SUMMARY

Large differences in relative amounts of auxin were found in different parts of Easter lily bulbs on November 13, four and a half months after harvest and after storage in moist peat moss at 70° to 85°F. The apical 3 mm. of the stem axis contained about one thousand times the concentration of auxin present in the scales and basal plate. The remainder of the stem contained one-fifth the relative amount of auxin in the apical meristem. During subsequent storage from November 13 to December 15 at 77°F. and with sufficient moisture for active growth, there was a continual decrease of auxin in the scales and in the stem. In the basal plate and stem tip there was an initial decrease followed by a definite increase of auxin. The possible relationships between auxin changes and growth responses of the bulbs are discussed.

auxin in the stem tissue was only about one-twentieth that found in the growing point. At this time the relative auxin concentrations of the several regions of the bulb were: (1) apical 3 mm. of stem axis, 110.5;

CELL GROWTH AND DIVISION IN LIVING ROOT MERISTEMS ¹

Robert T. Brumfield

KNOWLEDGE CONCERNING the processes of growth and division of individual meristematic cells as they develop to maturity is clearly of importance for an understanding of the factors involved in cell differentiation and plant morphogenesis. Little is known about these processes in multicellular tissues except from fixed and sectioned material, the limitations of which are obvious. The most significant evidence can be obtained only by the use of living tissue wherein the same cell can be observed throughout its development. Recently a technique has been devised whereby growth and division of single cells in living root meristems can be studied. Results obtained by the use of this method are reported in this paper.

Sinnott (1939) has pointed out that the epidermal cells in root meristems of many small-seeded grasses can be clearly seen in the living condition since the root cap consists of but a few loose cells at the extreme tip. Seedlings are grown on microscopic slides covered with moist lens paper and kept in covered Coplin staining jars with a little water at the bottom of the jars. The growing seedling is flooded with water, covered with a supported cover glass, and placed under the microscope for observation of the growing root. By means of camera lucida drawings made at successive intervals of time, it is possible to observe cell division and growth.

Using this technique, Sinnott and Bloch (1939a) made a study of root hair formation in *Phleum pratense*, *Poa trivialis*, *Sporobolus cryptandrus*, and *Chloris gayana*. It was found that in *Phleum* and *Poa* the last cell division is an unequal one which results in a small trichoblast or root hair-forming cell and a larger cell which does not form a root hair. The trichoblast is always toward the tip of the root and the hairless cell toward the base. During elongation, the trichoblasts grow less than the hairless cells. In *Sporobolus* and *Chloris* the divisions were found to be more nearly equal and both daughter cells may form root hairs.

In a later paper (Sinnott and Bloch, 1939b), especial attention was given to "sliding growth" and differential wall growth, using *Phleum* and *Sporobolus* for observation. All the evidence obtained indicated that sliding growth does not occur. Differential wall growth was apparent in that: (1) parts of the walls of hairless cells opposite trichoblasts grow less than parts opposite other hairless cells; (2) under certain conditions, cells grow more in the middle portions than near the ends; (3) the end of a cell toward the base of the root attains its final size sooner than the apical end of the same cell.

¹ Received for publication March 23, 1942.

The author wishes to express his appreciation to Professor E. W. Sinnott of Yale University for criticisms and suggestions during the course of this investigation.

This paper is part of a dissertation presented to the Graduate School of Yale University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

These observations show that the differences in size of large cells and small ones are a result not only of unequal divisions but also of differences in their growth rates. The present investigation was undertaken to determine the growth rates of single cells and their descendants as they pass from the meristematic condition to maturity, thus obtaining more

precise data on the differences in growth of hairless cells and trichoblasts.

MATERIALS AND METHODS.—*Phleum pratense* was chosen for the experiment, because in this species trichoblasts and hairless cells are clearly differentiated. Seed was obtained from the United States Department of Agriculture, Bureau of Plant Industry, Division of Forage Crops and Diseases, Washington, D. C., through the courtesy of M. A. Hein. The seed was from the 1940 harvest and was of a strain designated as F. C. no. 22,608. The seeds were evidently heterogeneous genetically, having a wide range in germination time and giving about 3 per cent albino plants.

There were several difficulties in the method of observation used by Sinnott and Bloch (1939a) which have been avoided in the present investigation by the use of a new technique. Their procedure requires that the root be put in a horizontal position for the period of observation. After a few minutes on the horizontal stage, the root twists somewhat, probably as a result of alteration in its position with respect to gravity, and does not grow normally (*cf.* Sinnott, 1939). Thus cells on the upper surface of the root at one observation period may, as a result of twisting, be turned to one side of the root at the next period. This behavior often makes it impossible to find the same group of cells at successive intervals of time. Moreover, it is difficult to make camera lucida drawings fast enough to obtain satisfactory growth curves for a group of rapidly growing cells, since the elongation of the root constantly changes the image of the cells in relation to the drawing. These difficulties were avoided in the present investigation by growing the seedling in such a way that it could be observed without changing its position, and photomicrographs were made rather than camera lucida drawings.

A chamber was constructed by cutting an opening about 20 mm. x 46 mm. in a piece of cardboard about 50 mm. x 77 mm., and 2 mm. thick, with the long axis of the opening at right angles to the long axis of the cardboard. One side of the opening was covered with a microscopic cover glass 24 mm. x 50 mm. and sealed with paraffin. A cover slip 24 mm. x 45 mm. was placed over the other side. Since the second cover slip was shorter than the opening in the cardboard, a space was left uncovered for gaseous interchange. Before the second cover was put in place, it was smeared with agar, a germinating seed placed near one end, and the agar and seedling covered with a strip of moist lens paper. The cover slip was put in place and sealed with paraffin, the seedling being inside the chamber thus formed. A few drops of water were introduced, and the lens paper acted as a wick keeping the seedling and agar moist (fig. 1). The cardboard was placed on the stage of a horizontal microscope with the long axis of the chamber in a vertical position, the seedling being at the upper end of the chamber and the cover glass bearing the seedling being nearest the objective. In this way the growing root was kept in the same position at all times, and photomicrographs could be taken without disturbing the growing seedling. The agar was of 0.25 per cent concentration and contained 0.25 gm. of NH_4NO_3 , 0.1 gm. of KH_2PO_4 , 0.1 gm. MgSO_4 and 0.05 gm. CaCl_2 per liter. The experiment was carried out at room temperature, about 25°C.

Photomicrographs were taken with a Bausch and Lomb type "H" camera in the horizontal position. A Bausch and Lomb mercury arc lamp with a water-

cooling cell and a Wratten filter number B-58 (green) served as the light source. The root was illuminated with this lamp only when photographs were being taken. At other times it was illuminated by overhead lamps of the usual intensity for laboratory rooms.

The seedling was allowed to grow for several hours to become adjusted to its new position, and then photographs were taken at half-hour intervals for a period of thirty and one-half hours, starting at 10:30 p.m., June 20, 1941. A 40X fluorite oil immersion objective and a 7.5 X eyepiece were used for the small cells close to the root apex. It was necessary, of course, that both the cover slip bearing the seedling and the agar layer be thin; otherwise the root would have been held beyond the focus of the objective. The thinness of the moist chamber made it possible to focus the condenser, giving better resolution in the photographs. A 10 X objective and a 15 X eyepiece were used to photograph the longer cells farther behind the root apex. Mineral oil was used as the immersion medium, and it was found unnecessary to remove the oil from the cover when changing from the immersion objective to the low power one. Negatives were taken on Super XX Panchromatic cut film $3\frac{1}{4}'' \times 4\frac{1}{4}''$ and enlarged in printing to give a magnification of 757 times for the small cells near the tip and of 412 times for the longer cells. Thus a successive series of photographs was obtained from which cell length could be easily measured. Measurements were made by placing the points of a small pair of dividers on each end of the cell at the juncture of its transverse and longitudinal walls and then transferring to a millimeter rule, readings being made to tenths of a millimeter. The data were later corrected to microns. The growing root was measured at each half-hour interval by removing the camera bellows and substituting an eyepiece fitted with an ocular micrometer for the one used in taking the photographs.

Although the root was not subjected to changes in position with respect to gravity, there was a tendency for the tip to rotate around the long axis of the root. This rotation carried cells photographed at an earlier period out of the microscope field on one side and brought cells not previously photographed into the field on the other side at a later period (compare figures 3C and 3D). This limited the number of cells which could be followed throughout development. Also, some inaccuracy in measurement of cell length resulted from slight differences in the level of focus at which successive photographs were taken, since the end walls of the epidermal cells are not always at right angles to the long axis of the root but may be somewhat oblique. The effect that an oblique end wall and different levels of focus may have on the apparent length of a cell in the photographs is shown

Fig. 3, A-E. Drawings of a group of epidermal cells and their descendants at successive intervals of time. Cell 5 is nearest the root apex and about 0.07 mm. behind it in A. A, June 20, 10:30 P.M. B, June 21, 4:30 A.M. C, June 21, 10:30 A.M. D, June 21, 5:30 P.M. E, June 22, 4:00 P.M. At the completion of division in each cell, the individuals of the resulting complex were designated by a letter, cells nearest the root apex being given the letter A, the next B, etc. Traced from photomicrographs with the aid of a pantograph X 284.

diagrammatically in figure 2. At focus *A* cell 1 would appear longer than at focus *B*; similarly, cell 2 would appear longer at focus *B* than at *A*. The percentage of error thus introduced is small, however, and decreases as the cell increases in length.

RESULTS.—The results are best presented by a series of drawings and growth curves. Figures 3A-E show the same group of meristematic cells at successive intervals during their development. In each case the apical end of the root is towards the bottom of the plate, and at the beginning of the experiment the group of cells was about 0.07 mm. behind the root tip (root cap not included). After the completion of division in each cell the individuals of the resultant complex were designed by a letter, as for example 11A, 11B, 11C, and 11D (fig. 3C), cells nearest the root apex being given the letter A, the next B, etc.

It is evident from the figures that cells near the tip undergo more division than those farther behind it. Thus cells 33 and 32 divided only once, each forming two daughter cells. Cells 10 and 11 divided twice, each giving rise to four daughter cells. Cell 5 divided three times, resulting in a complex of seven cells (the basal cell did not divide at the time of the third division). Cells farther from the tip than 33 and 32 did not divide.

The growth curve for cell 11 and its resultant complex of cells is shown in figure 4. The logarithm of cell length is plotted against time. At the beginning of the experiment, cell 11 was single (fig. 3A). Between 12:00 A.M. and 12:30 A.M., June 21, it divided (fig. 3B). Between 7:00 A.M. and 7:30 A.M., June 21, the more basal of the two daughter cells divided; between 8:30 A.M. and 9:00 A.M., June 21, the more apical of the two daughter cells formed at the first division divided, giving the complex four cells (fig. 3C). No further divisions occurred, and the complex reached its final size consisting of four cells. Two of them (11A and 11C in figure 3C) were trichoblasts and two (11B and 11D, figure 3C) were hairless cells. Measurements were made of one longitudinal wall (the wall between cell row A and cell row B in figures 3A-E) of the whole complex regardless of the number of cells into which it divided. The times at which divisions occurred are indicated on the curve in figure 4 by arrows. The gaps in the curve are due either to the cell being out of focus, making measurement impossible, or to the rotation of the root which carried the cell out of the microscope field for a short period. The wavy character of the lower part of the curve is probably due to different levels of focus and an oblique end wall rather than to rhythms of elongation. Variation in the level of focus tends to occur at more or less regular intervals, since the tip of the growing root moves downward in a spiral fashion. This movement results in the tip being close to the cover slip at some periods and farther away at others, thus causing periodic variation in the level of focus.

As seen from figure 4, the cell and its resultant complex passed through two growth phases, elongation proceeding at a constant exponential rate in

both. These two phases are represented by the linear parts of the curve. In the first phase (the lower part of the curve) the rate was about 5.4 per cent per hour,² this rate remaining constant for about fourteen hours. At the end of this phase, the rate began to increase and continued to do so until a second constant rate was established, this rate being about 41.2 per cent per hour. The period of increasing rate lasted for about nine and one-half hours and apparently represents a transition from the first growth phase to the second. In the second phase, the growth rate remained constant at 41.2 per cent per hour. This phase was of short duration, lasting for about four hours only. At the end of the second phase the growth rate fell off to zero quickly.

Cell division occurred only during the first growth phase. At the end of the first phase the vacuoles increased in size, doing so earlier in the long hairless cells than in the shorter trichoblasts. Root hairs began to appear as soon as the complex reached its final length.

Growth curves for cell complexes 5, 8, 10, 11, 16, and "31-32" are shown in figure 5. It was desired to compare the growth of complexes in all parts of the meristematic region. In the basal part of the meristem, however, trichoblasts and hairless cells had already been differentiated. Growth in either of these two types of cells alone would probably not be comparable to a complex consisting of both types. For this reason cells 31 and 32 were measured together as a single complex, cell 31 being a trichoblast and 32 a hairless cell (fig. 3A). The longitudinal wall measured in each complex was that one between cell row A and cell row B (fig. 3A). The walls measured in cells 5 and 8 were the same length at the beginning of the experiment, and the two curves coincide in the parts representing the first phase of growth. The growth rate of cell 8 increased sooner than that of cell 5, however. Neither of them completed its growth during the period of observation.

As seen from figure 5, the growth curves for all complexes are quite similar, differing only in the length of that part of the curve which represents the first phase of growth. This length evidently depends on the position of the cell or complex with respect to the root apex at the beginning of the experiment, the first phase being longer for those cells near the root tip. This suggests that the first phase of growth occurs in a definite region or zone and each complex begins the transition to the second phase when it is carried out of this zone by the elongation of cells apical to it. Since the transition period and the second phase are similar for all complexes, these processes must also occur in definite zones. Thus the transition occurs in a second zone lying immediately behind the first zone and the second growth phase takes place in a third zone which lies behind the second. Elongation ceases at the end of the third zone.

² Calculated from the formula $A = Pe^{rt}$, in which *A* is the size after a given time, *P* the size at the beginning, *e* the base of the natural logarithms, *r* the rate, and *t* the number of time intervals.

TABLE 1. Showing the distance behind the root apex at which different complexes completed the first growth phase, the distance at which they began the second growth phase, and the distance at which elongation ceased.

Complex number	First growth phase completed	Second growth phase began	Elongation ceased
"31-32"	.14 mm.	.32 mm.	.97 mm.
16	.15 mm.	.33 mm.	1.01 mm.
10	.14 mm.	.31 mm.	.95 mm.
11	.15 mm.	.31 mm.	.95 mm.
8	.13 mm.	.30 mm.	—
5	.13 mm.	—	—
Average	.14 mm.	.31 mm.	.97 mm.

The length of each of these zones was determined by reference to the growth curves shown in figure 5 and by measurements made from the photographic record. The time at which a given complex passed from one zone to another was marked by a change in its growth rate, and the distance from the apical end of the complex to the tip of the root was measured from photographs taken at the time the change in rate occurred. Complex 10 passed into the second growth zone at about 11:00 A.M., June 21, as evidenced by an increase in its growth rate (fig. 5). The apical end of the complex was about 0.14 mm. behind the root apex (root cap not included) at that time, as measured from the photographic record. Thus complex 10 passed from the first zone to the second when it was about 0.14 mm. behind the root apex. Obviously, the basal end of any complex enters the second zone first. On doing so, the growth rate of the whole complex apparently increases, although the apical end may be still growing at the rate in zone 1. At the time the growth rate of the whole complex first shows an increase, the border line between the first and second zones lies somewhere between the two ends of the complex rather than at its apical end, and measuring to the apical end of the complex makes zone 1 appear somewhat shorter than it actually is. This does not introduce an appreciable error, however, since the complex is rather short at this time. At about 8:30 P.M., June 21, the whole of complex 10 had entered the third growth zone as indicated by the growth rate becoming constant (fig. 5). The apical end of the complex was about 0.31 mm. behind the root apex at that time, showing that the border line between zones 2 and 3 was about 0.31 mm. behind the root apex. The complex stopped elongation at about 4:00 A.M., June 22, indicating that the whole complex had just passed out of zone 3. At that time, the apical end of the complex was about 0.95 mm. behind the root apex, the basal edge of zone 3 being at this point. The growth rate falls off very quickly at the end of zone 3. As appears later, the rate decreases from its maximum to zero in probably less than half an hour, the time interval between measurements. Therefore, it was not possible to determine here either the point at which the decline in growth rate first began or the length of the region in which it occurred. Since the measurement was made

at the time that elongation ceased, the region in which the decline in growth rate occurred is included in zone 3.

The results of similar measurements for complexes 5, 8, 11, 16, and "31-32" are shown in table 1. The measurements were difficult to make accurately since the times at which the changes in growth rate occurred could not be determined exactly. However, the agreement between measurements for different complexes is fairly close.

The relative lengths of the different zones and the growth rate in each is made clear by reference to the diagram shown in figure 6. The graph shows the growth rates of cells and their resultant complexes, expressed in per cent per hour, plotted against their distances from the root apex. Ordinates are growth rates, and abscissae are distances from the apex (root cap not included). Solid lines indicate growth rates as determined from the growth curves. Dotted lines indicate estimated rates in regions where it was impossible to obtain an accurate determination. As seen from the graph, all cells within a zone extending from the root tip to about 0.14 mm. behind it grow at an exponential rate of about 5.4 per cent per hour. In the next 0.17 mm. (from 0.14 mm. to 0.31 mm.) the rate increases from 5.4 per cent per hour to about 41.2 per cent per hour. Cells in the next 0.66 mm. (from 0.31 mm. to 0.97 mm.) grow at a constant rate of about 41.2 per cent per hour. The diagram of the root tip below the graph is drawn to the same scale as the abscissae of the graph, and it shows the relative proportions of the three growth zones. Cell division occurs only in zone 1 under normal conditions.

Each cell becomes farther and farther removed from the root apex because of the elongation of intervening cells. As its distance from the root apex increases, the cell passes through zones 1, 2, and 3, successively. When the cell passes over the basal edge of zone 3, it ceases to elongate and becomes a part of the mature root. The length of each zone is apparently constant (table 1), and the growth rate in each zone evidently remains constant, since the growth curves for all complexes are similar (fig. 5). The rate at which cells pass out of zone 3 and become a part of the mature root must also be constant, since this rate could vary only as a result of changes in the length of the growth zones or variations in the cell growth

rates. Since root growth results only from the activity of the growing point, the rate of root elongation should be the same as the rate at which cells pass over the basal edge of zone 3.

The rate at which cells pass over this point and reach their final size could readily be determined by reference to the growth curves shown in figure 5 and measurements made from the photographic record. Complex 31-32 ceased growth at about 5:30 P.M., June 21 (fig. 5), indicating that the apical end of the complex had just passed through zone 3 at that time. Complex 10, which was nearer the root apex than 31-32, stopped elongating at 4:00 A.M., June 22, indicating that its apical end had then just passed through zone 3. Thus, ten and one-half hours were required for the length of cell wall between the apical end of complex 31-32 and the apical end of complex 10 to pass out of zone 3. The distance between these two points, measured from photographs taken at the time it had reached its final length, was 2.76 mm. Thus cells passed over the basal edge of zone 3 at a rate of 0.263 mm. per hour, this being the rate at which mature cells were added to the length of the root as a whole.

The results of the measurements of root growth are shown graphically in figure 7, root length being plotted against time on an arithmetic grid. The figure shows that total root length increased at a constant rate of about 0.266 mm. This agrees very well with the rate at which cells passed over the basal edge of zone 3 (0.263 mm. per hour), considering possible error in determining the two rates. The constant rate of root elongation shows that the growth rate in each zone and the length of each zone remained remarkably constant for the duration of the experiment, since variation in either would obviously influence the rate of root elongation.

The origin of cells of different size, such as trichoblasts and hairless cells, is of especial interest in this study. Such cells were formed in complex 11 by unequal divisions which are almost always the final ones (fig. 3C, cf. Sinnott and Bloch, 1939a). The contents of the trichoblasts are more dense and their basal transverse walls are convex towards the base of the root (cf. Leavitt, 1904; Sinnott and Bloch, 1939a).

Fig. 4-10. Growth of cells in a living grass root.—Fig. 4. Growth curve for a single epidermal cell and its descendants as it passed from the meristematic condition to maturity (cell number 11 in figures 3 A-E). Logarithmic plotting. Arrows indicate time of division.—Fig. 5. Growth curves for six epidermal cells and their descendants located at different distances from the apex of the root. The cells and their resultant complexes are numbered as in figures 3, A-E. Cell 5 was nearest the apex and "31-32" farthest from it. Cells 5 and 8 did not complete their growth during the period of observation. Logarithmic plotting.—Fig. 6. Diagram showing the growth zones observed in a living root of *Phleum pratense* and the growth rates of epidermal cells in each zone. The graph shows the growth rate of the cell plotted against its distance from the root apex. Solid lines indicate the actual rates as determined from growth curves; dotted lines show the estimated rates in regions of the root where it was impossible to obtain an accurate determination. Below the graph is a diagram of the root drawn to the same scale as the abscissae of the graph. In zone 1 the growth rate remains constant at about 5.4 per cent per hour, in zone 2 it increases to about 41.2 per cent, and in zone 3 it remains constant at 41.2 per cent, falling off to zero in the basal end of zone 3.—Fig. 7. Growth curve for a living root of *Phleum pratense*. Arithmetic plotting.—Fig. 8. Growth curves for each of the four descendants of a single epidermal cell which formed trichoblasts and hairless cells (cell 11 in figures 3, A-E). 11a and 11c are trichoblasts while 11b and 11d are hairless cells. Logarithmic plotting.—Fig. 9. Growth curves for each of the four descendants of a single epidermal cell which did not form trichoblasts (cell 10 in figures 3, A-E). Logarithmic plotting.—Fig. 10. Growth curves from figures 8 and 9 superimposed for better comparison. The curves are superimposed in such a way that the points at which growth ceased coincide.

The unequal division is largely responsible for the smaller size of the trichoblasts but it also appears that they elongate less than the hairless cells. Growth curves were plotted for the individual cells of complex 11 so that growth in the two types of cells could be compared (fig. 8). Growth curves for the individual cells of complex 10, none of which became trichoblasts, were also plotted (fig. 9). Measurements were not begun until two hours after their formation, since new cell walls do not show up well in the photographs. The last divisions in both complex 10 and 11 occurred near the end of the first growth phase, and consequently the growth curves for the individual cells of each complex represent little of the first growth phase.

As is evident from figure 8, the trichoblasts did not elongate as much as the hairless cells (cf. Sinnott and Bloch, 1939b). After the unequal division, cell 11A was one-third as long as its sister cell 11B, but after reaching their final size cell 11A was only about one-sixth the length of 11B. Similarly, cell 11C was about two-fifths the length of its sister cell 11D at the time of its formation, but after growth was completed, cell 11C was about one-third the length of 11D. All four daughter cells elongated nearly the same amount in complex 10.

The growth curves for the individual cells of complex 11 and complex 10 were superimposed in such a way that the points at which growth ceased coincided (fig. 10). The curves for all the cells of complex 10 and for the hairless cells of complex 11 are quite similar, falling within a rather narrow band. The trichoblasts evidently differ from the others in that they tend to grow more slowly during the transition period, and that for them the second growth phase is of somewhat shorter duration.

Nothing indicating the occurrence of sliding growth has been observed during the course of this investigation. If cells in adjacent rows were to slide along one another during growth, then transverse walls of cells in adjacent rows should occasionally move past one another. Also, the distance between transverse walls in adjacent cell rows should be observed to decrease in some cases. Transverse walls in adjacent rows were never seen to move past one an-

other and the distance between such walls always increased. This is strong evidence that "sliding growth" does not occur in this tissue (*cf.* Sinnott, 1939; Sinnott and Bloch, 1939b).

If the walls of neighboring cells do not slide along each other, then the points at which end walls of cells in adjacent rows meet the longitudinal wall of a given cell can be used as marker points to divide it into smaller units. In this way growth curves can be plotted for different parts of a single cell and growth in these parts compared. Cell 11D, a long hairless cell, was chosen for this purpose. It was divided into apical, middle, and basal portions which were marked by end walls in complex 10, all cells of which were hairless ones (fig. 3D). This choice was made to avoid as much as possible any influence of neighboring trichoblasts. The basal part of cell 11D consisted of that part of the cell wall extending from the basal end wall of cell 11D to the basal end wall of cell 10C. This part is the same as the apical portion of cell 10D. The middle part of cell 11D was marked by the end walls of cell 10C and its growth curve is of course the same as that for cell 10C. The apical part of cell 11D consisted of that part between the apical end wall of cell 10C and the apical end wall of cell 11D, this being the same as the basal part of cell 10B. Measurements were begun when the cell walls became sufficiently well defined to show clearly in the photographs, about two hours after the last division, so during most of the period of measurement the cell was in the transition period and the second growth phase.

Growth curves for the three parts of cell 11D are shown in figure 11 and are superimposed in figure 12. The apical end of the cell evidently grew somewhat more than the middle part, and the middle part somewhat more than the basal end, although the differences are slight. The differences in the curves are greatest in those parts representing the transition from the first phase to the second, while those parts of the curves representing the second growth phase are essentially parallel. Intercellular relationships which may have affected the growth of different parts of cell 11D could not be determined, since rotation of the root made it impossible to study the growth of cells in rows adjacent to complex 10 and

Fig. 11-13D. Growth of different parts of the same cell. —Fig. 11. Growth curves for different parts of a single cell (cell 11d in figure 3D) marked by end walls of a cell in an adjacent cell row (cell 10 in figure 3D). A, is the apical part; M, the middle part; and B, the basal part. Logarithmic plotting.—Fig. 12. Growth curves from figure 11 superimposed for better comparison. The curves are superimposed in such a way that the points at which growth ceased coincide.—Fig. 13, A-D. A single cell (11D in figure 3D) drawn at one-hour intervals covering the period from the time that all parts of the cell were growing at the maximum rate until the cell reached its final size. Different parts of the cell are marked by cross walls in adjacent cell rows. The apical end of the cell is toward the bottom of the figures. A, June 21, 11:30 P.M. B, June 22, 12:30 A.M. C, June 22, 1:30 A.M. D, June 22, 2:30 A.M. Traced from the photomicrographs. X 313.

complex 11. It is clear, however, that differential wall growth does occur and that different parts of the same cell may be growing at quite different rates at the same time. Thus, as seen from figure 11, the basal end of cell 11D completed its growth at about 12:00 midnight, June 21, while the apical end of the same cell was still growing at its maximum rate. This differential growth of the cell can be seen more clearly in figures 13A-D which were traced from photographs taken at one-hour intervals covering the period from the time that all parts of the cell were growing at the maximum rate until the cell reached its final size; i.e., from 11:30 P.M., June 21, to 2:30 A.M., June 22. The series shows that the basal end stopped growing first, the middle part next, and the apical end last, the cessation of growth passing along the cell from base to apex (cf. Sinnott and Bloch, 1939b).

Figure 11 shows that the growth rate of each part of the cell fell off to zero abruptly, doing so in the case of middle part of cell 11D in about one hour. This time interval is about the same as that required for this part of the cell to pass out of zone 3, since cells pass out of this zone at about 0.263 mm. per hour, and since the middle part of cell 11D was about 0.22 mm. in length when it reached its final size. A similar agreement between the time required for the cell or its derivatives to pass out of zone 3 and the length of the period of declining growth rate can be shown for all cells measured. This being so, the decline in growth rate seen at the ends of the growth curves shown in figures 5, 8, 9, and 11 evidently results primarily from the fact that shorter and shorter lengths of the cells or complexes are growing as they pass out of zone 3, rather than to a lower rate of growth in the basal part of the zone. Thus each cell evidently grows at its maximum rate up to very near the end of zone 3, the growth rate falling off to zero in a very short region. The suddenness with which growth ceases evidently has an important bearing on the factors controlling cell growth. It was impossible however, to determine how rapidly the decline took place, the interval between successive measurements being too long.

Similar results were obtained in an earlier experiment using the same technique, also on *Phleum pratense*. The photographs were taken at two-hour intervals, but unfortunately they did not include a sufficient length of the root apex to allow development to be followed until the cells reached their final size; i.e., only a part of zone 3 was included in the photographs. In zone 1 the rate was constant at about 6.5 per cent per hour and in zone 3 at about 56 per cent per hour. The root as a whole elongated at about 0.39 mm. per hour. Zone 1 extended to about 0.16 mm. behind the root apex (root cap not included). The higher rates observed in the earlier experiment were probably not due to differences in environmental conditions, which were about the same in the two experiments, but to genetic or possibly size differences in the two seedlings.

DISCUSSION.—The results reported here evidently have an important bearing on such problems as the growth processes in the root apex; growth regions in the root meristem; differential cell growth and cell differentiation; rhythmic growth of organs and cells; the physiology of cell elongation (cf. Heyn, 1940); and the differential effect of heteroauxin on root elongation and meristematic activity in producing lateral roots (cf. Albaum and Commoner, 1941).

Fig. 14, A-C. Diagrams showing the amount of growth made by 0.1 mm. sections of a *Phleum pratense* root. A shows the position of the sections at the time of marking, while B and C show the amount of growth made after 4 and 7½ hours respectively. Dotted lines indicate the three growth zones as shown in figure 6.

Space does not permit a discussion of all these aspects however, and the discussion will be limited to those problems to which the present investigation is more directly related.

Growth processes.—Two distinct processes are evidently involved in growth of this tissue. During the first phase of growth the cell elongates at a relatively low but constant exponential rate. Divisions occur during this phase, dividing the cell into a complex of smaller units, but without markedly influencing the growth rate of the cell or its resultant complex. As the cell or complex grows, it becomes farther removed from the root apex because of the elongation of cells apical to it. When the cell reaches a distance of about 0.14 mm. behind the root apex, cell division ceases, and the first growth process begins to be supplanted by a second and more rapid process of elongation, the growth rate gradually increasing until the new constant rate is established. During the period of increasing growth rate the vacuoles within the cell become larger and coalesce. This continues during the second growth phase, and finally a single large vacuole fills the center of the cell, and the cytoplasm extends as a thin sheet next to the cell wall. Thus it appears that in the first growth process cell elongation results primarily from the production of new protoplasm accompanied by the formation of new cells, while in the second process the cell elongates primarily as a result of increase in volume of its vacuoles and the formation of new cell wall material (cf. Priestley, 1929). The period of increasing growth rate apparently represents a transition from one process to the other.

That new protoplasm is formed primarily in a region close to the tip is also suggested by the work of Reid (1941) on cowpea roots. In these it was found that throughout growth the water content of the cell

is proportional to its volume, while its dry weight increases most rapidly in a region close to the root apex.

Growth regions.—In the older method used to detect regions of most rapid growth, the growing point is marked with India ink at regular intervals along its length. The transverse section thus marked off, which later shows the most growth, indicates the region of greatest elongation. In a typical experiment of this type, Sachs (1882) made transverse marks at one millimeter intervals behind the apex of a primary root of a *Vicia faba* seedling. Twenty-four hours later it was found that the greatest elongation had occurred in a one-millimeter section lying about 3 mm. behind the root apex. It was concluded from this that the region of most rapid growth is a rather short one.

As seen from figure 6, the region of most rapid elongation in *Phleum pratense* occupies most of the length of the growing point. It can be shown, however, that this is not in disagreement with the results obtained by the marking experiments. Photographs taken at 9:30 P.M., June 21, were marked with transverse lines, the distance between the lines being such as to correspond to 0.1 mm. on the growing root. It was possible to determine in photographs taken at later periods the amount of growth made by each 0.1 mm. section, using cross walls as reference points. Essentially, this amounts to duplicating Sachs' marking experiment in a much more accurate manner. The position of each 0.1 mm. section marked off at the beginning is shown diagrammatically in figure 14A, and the length of each section after four and seven and one-half hours is shown in figures 14B and 14C respectively. Dotted lines indicate the growth zones as shown in figure 6.

Four hours after marking, section 4 had made the greatest growth, since it grew by the higher rate in zone 3 for a longer period than the others. Section 5 elongated less than section 4, since it remained in zone 3 for a shorter time. Similarly, section 6 was shorter than 5, 7 shorter than 6, etc., and section 11 showed no growth, since it had completed elongation at the time of marking. Section 3, being in zone 2 at the time of marking and, consequently, elongating at a lower rate than section 4, did not grow as rapidly as section 4 during the four hour period. Therefore, it was shorter than section 4. Seven and one-half hours after marking, however, section 3 was the longest, since it grew for a longer period than 4, while section 2 was just beginning to grow by the higher rate in zone 3. Sections 6, 7, 8, 9, and 10 were no longer after seven and one-half hours than after four hours, since they passed out of zone 3 during the first four hours. Obviously, if measurements were made still later, section 2 would be the longest. The amount of growth made by sections marked off in the manner described evidently depends on the position of the section with respect to the growth zones and on the time elapsing between marking and later measurement. Thus, this type of experiment is of little value in detecting growth in different regions of

the growing point unless measurements are made at frequent intervals.

Differential cell growth.—The differential growth of trichoblasts and hairless cells is of especial interest, since it has a bearing on the problem of cell differentiation. The results of this investigation show that the difference in growth rate in the two types of cells is greatest in zone 2, where a transition from protoplasmic synthesis to vacuole enlargement apparently occurs. The trichoblasts, which are more richly protoplasmic, continue growth in zone 2, at more nearly the rate of growth which occurs in zone 1, while the growth rate of the hairless cells increases. Associated with the differences in growth is the fact that vacuoles appear in the hairless cells sooner than in the trichoblasts. The differences in behavior of the two types of cells may be due to differences in the structure of their walls, since, as Sinnott and Bloch (1939b) have shown, the walls of the trichoblasts appear to be more rigid than those of the hairless cells. It is also possible that the trichoblasts continue protoplasmic synthesis for a longer period than the hairless cells. This would account for the slower increase in growth rate of the trichoblasts and for the earlier appearance of large vacuoles in the hairless cells. As a third possibility, it may be that growth by vacuolation is induced by some stimulus passing from the base of the root and that the trichoblasts and hairless cells respond to the stimulus differently because of differentiation occurring at the time of the unequal division. Although no conclusions can be drawn at the present time as to why the two types of cells differ during growth, it is clear that the difference in growth rate appears immediately after the division forming them. As evidenced by the curves in figures 11 and 12, later growth in both types of cells is very nearly the same.

Rhythmic growth.—Kellicott (1904) working with germinating bulbs of *Allium cepa* reported that root elongation was rhythmic, exhibiting three waves of elongation in a twenty-four-hour period. Friesner (1920) also observed rhythms of elongation in roots of a variety of plants, most comprehensive results being reported for *Pisum sativum*. Two or more waves per twenty-four-hour period were reported, periods of maxima and minima being associated with the time of seed germination. Cell division showed similar rhythms, maxima falling at periods of minimum root elongation and *vice versa*. It was concluded from this that the energy of the growing root was directed at one time toward cell division and at another toward cell elongation. It is evident from figure 7 that, in the root observed here, no rhythms of elongation were exhibited by the root as a whole, and from figure 4 that the growth of the cells is not influenced by their division but is continuous at a constant rate. It is possible that here the periodic lighting of the root for photography may have caused responses which masked any tendency toward rhythmic growth. Yet it appears, *a priori*, that rhythms in cell division should have little effect on the rate of root elongation, since division occurs only in a region

whose growth adds but little to root length (cf. Kojima, 1928). The greater part of root elongation results from growth in length of cells in zone 3 where cell division does not occur. As seen from figure 5, elongation of cells in this region is not rhythmic, all cells in this region growing at the same constant exponential rate.

Abele (1936), in a statistical study based on measurements of cells in fixed material, concluded that in meristematic tissue cell growth occurs in two stages. Shortly after telophase, "Streckungswachstum" occurs during which the cell increases to the average size of the resting cells. No growth occurs during the resting stage. "Teilungswachstum" takes place following the resting stage, the cell reaching its maximum size by late prophase and no further growth occurring until after division is completed. It is clear from figure 4 that in the living root observed here no growth rhythms were detected, cell elongation continuing at a constant rate regardless of its division. Moreover, the behavior described by Abele would obviously involve sliding growth, which apparently does not occur in this tissue.

SUMMARY

Phleum pratense seedlings were grown in a specially constructed moist chamber, and groups of meristematic cells in the root tips were photographed at intervals as they developed to maturity. Growth curves of individual cells and cell complexes resulting from their division were plotted from measurements of cell length made from the photographs.

Each cell or its resultant complex passes through

two phases of growth, elongation proceeding at a constant exponential rate in each. In the first phase, the cell or complex elongates at about 5.4 per cent per hour. At the end of this phase, the growth rate increases from 5.4 per cent per hour to about 41.2 per cent per hour. In the second phase the rate remains constant at 41.2 per cent per hour, the growth rate falling off to zero at the end of this phase. Cell division occurs only during the first phase.

The first phase of growth appears to be primarily concerned with the production of new protoplasm and the second with vacuole enlargement. The period of increasing growth rate apparently represents a transition from one growth phase to the other.

The first phase occurs in a zone extending from the root tip to 0.14 mm. behind it (root cap not included). The transition occurs in a second zone which extends from 0.14 mm. behind the root tip to 0.31 mm. behind the tip. The second growth phase takes place in a zone extending from 0.31 mm. behind the root tip to 0.97 mm. behind it. In the basal end of this zone the growth rate falls off to zero rapidly.

Trichoblasts elongate less than hairless cells. The growth rate of the trichoblasts increases more gradually than that of the hairless cells during transition from protoplasmic synthesis to vacuolation.

No evidence of "rhythmic" growth was observed in root elongation, and the process of division did not appear to influence the rate of cell elongation.

CATECHOL AGGREGATES IN THE VACUOLES OF CELLS OF ZINC DEFICIENT PLANTS ¹

Howard S. Reed and Jean Dufrenoy

CELLULAR INCLUSIONS have, for over a century, received attention from plant cytologists. The results of many investigations which employed either chemical or physical criteria agree that colloids of one sort or another are present in plant cell vacuoles. Evidence of their physiological importance which is now at hand promises to elucidate some phenomena having great significance for the activity of the cell. Precise studies have shown that differences in their states of hydration and dispersion are intimately related to health and disease. They are also plainly important in determining the water-holding capacity, the absorption of "vital dyes," and the viscosity of the cell sap.

The present paper presents new data on the formation of catechol-lipoidic aggregates in the vacuolar sap and shows how they are related to certain nutrient deficiencies of plants. Although phenolic materials of this type have long been known in many plants, their relation to the physiology of the cell has been imperfectly understood. On account of their small size and their indifference to the majority of aniline stains, bodies of this class have been frequently overlooked or wrongly identified as parasitic myxomycetes, chytrids, or other organisms.

Viala and Sauvageau who, in southern France, investigated the vine disease, known as Brunisure, described (1892 a and b) the cell inclusions as plasmodia of a myxomycete. Prunet, who designated (1894) similar inclusions as chytrids, e.g. *Cladochytrium viticolum*, initiated, apparently, a chytrid fad which prevailed for several years and subsequently reappeared from time to time. Although these identifications as organisms were wrong, they did establish the important fact that these vacuolar inclusions were associated with a diseased condition in the plant. Massee, who had originally succumbed to the chytrid fad, realized eventually (1895) that the inclusions previously described as chytrids were "tannin vesicles" of the sort described by Klercker (1888) and opened the road for further studies.

Ducommet (1900) corrected the erroneous idea of a plasmodial parasite in vines affected with Brunisure by showing that the vacuolar inclusions were aggregates of material which previously had been dispersed in the vacuolar sap. He observed that cells in the vine leaves affected with Brunisure contained both small and large spherical bodies and that they might coalesce. They had enveloping membranes and their contents might appear homogeneous or vacuolated. His microchemical tests showed that they were strongly impregnated with tannin, insoluble in fat solvents, and soluble in sodium hypochlorite.

The occurrence of globular inclusions of this type in the cell vacuoles of plants affected by nutrient

deficiencies was slow in receiving recognition. We have called attention (Reed and Dufrenoy, 1934 and 1935) to globular refringent inclusions of this type in cells of orange leaves showing mottling due to zinc deficiency. These vacuolar inclusions showed a certain amount of heterogeneity, having a central core of phenolic material and an enveloping layer of phytosterol material. We assumed the latter to represent an unused residue in those cells whose synthetic power was seriously impaired. We subsequently showed that treatments which restored the leaves to a healthy condition were characterized by the absence of those globular refringent inclusions.

Coacervates of this sort are associated with virus disease of plants. Dufrenoy (1942) has described them in the perivascular parenchyma cells of sugar cane affected with Chlorotic Streak, as well as in senescent canes.

Vacuolar aggregates of lipoidal nature occur in root cells invaded by endophytic mycorrhizas (McLuckie and Burges, 1932). If the globules possessed a central core of non-lipoidic material, possibly catechol (as their reactions suggest), further investigation should yield interesting results because of their importance in the physiological reactions of infected cells. The state of nutrition of the mycorrhizal cell has an intimate relation to the formation of vacuolar aggregates of phenolic material, as demonstrated by photomicrographs of cells which came from the roots of orange trees showing definite responses to soil treatments (Reed and Frémont, 1935). The aggregates of phenolic material occurred chiefly in cells in which the fungus lived parasitically rather than symbiotically.

The formation of these inclusions as a reaction to invasion by parasitic organisms has been recently demonstrated by Metcalfe (1941) who has described vacuolar inclusions (Y-bodies) in the ray-cells of willows attacked by parasitic bacteria. Although he misinterpreted certain details, he saw aggregates similar to those we have studied, if one may judge from his illustrations and descriptions of their reactions to micro-chemical reagents. Dufrenoy (1942) has described catechol aggregates of this type in cells at the margins of lesions produced in sugar cane by *Colletotrichum falcatum*.

It is now apparent that inclusions of catechol are related to at least three types of functional derangements, namely: (1) a deficiency of nutrients (using the term "nutrient" in a broad sense); (2) virus diseases; (3) attacks of parasitic organisms.

Cells of leaves showing symptoms of zinc deficiency commonly exhibit a condition in which the colloids of the vacuolar sap occur as flocculi floating in the liquid phase. The flocculi have a tendency to form globular aggregates which, on account of their uniformity, have been mistaken for micro-organ-

¹ Received for publication March 31, 1942.

isms; however, they may coalesce to form larger aggregates. The formation of colloidal globules by a process of desolvation or "unmixing" may be readily observed when living cells of affected plants are examined in neutral red solution. Figure 1 shows an example wherein the globules (represented by heavy shading) have separated out from the central vacuolar solution (represented by light shading) by the

sap. In the upper drawing we see the result of "vital staining" with neutral red or methylene blue. The positively charged dye accumulated in the spherical mass of colloidal material which shows a deeply stained ring. In the lower drawing we see the result of the application of Gomori's technique for PO_4^- anions. The negatively charged anions were dispersed throughout the saline vacuolar solution

Fig. 1-2.—Fig. 1. A representation of a living cell, stained with neutral red, featuring a case of syneresis, where the central vacuolar solution (featured light grey) is surrounded by a number of peripheral smaller vacuoles, wherein the colloidal material responsible for the absorption of neutral red has become concentrated, accounting for the much deeper staining of the solution (featured black).—Fig. 2. A schematic representation of the distribution of cations and anions in a vacuolar solution after syneresis and condensation of the colloids into a globular mass. The upper drawing features a living cell after being vitally stained with a basic dye. The lower drawing features a cell after being treated with Gomori's technique for PO_4^- . For further comment see text.

process of syneresis. When the process of desolvation affects only a portion of the colloidal material in the vacuole, it results in the formation of a coacervate instead of a generalized syneresis.

The formation of vacuolar precipitates when a cell is placed in contact with "vital dyes" is considered by Guilliermond (1941), not as flocculation, but as the production of coacervates due to the attraction between the positively charged dye and the negatively charged colloid. The anions are concomitantly dispersed in the vacuolar sap. The phenomenon is illustrated diagrammatically by figure 2, which represents the state of the vacuolar colloids following inner syneresis and the formation of a large spherical mass which floated in the vacuolar

(heavily shaded), whereas the central mass of colloidal material was devoid of PO_4^- ions.

Recent advances in cyto-technique and in micro-physical chemistry have afforded a vast amount of new information about these vacuolar inclusions (Dufrenoy and Reed, 1942). The papers on the cytological significance of these complex aggregates by Guilliermond and his co-workers and by de Jong (1929) on their physico-chemical significance have contributed additional evidence of their importance. The results of our subsequent work, which are reported in this paper, demonstrate that these complex bodies, called coacervates or aggregates, occur in the post-meristematic cells of root-tips, buds, and leaves of plants whose development was retarded owing to

a deficiency of zinc. These coacervates were seldom found in healthy plants. This work was done by the technique which Guilliermond has called "convergent technique," together with certain modifications which the authors have worked out and will describe below. Our observations agree well with the data on coacervates published by de Jong and on the reactions of catechols with vital dyes published by Guilliermond.

It seems evident from the works just cited that these bodies are formed by a process of coacervation which we define as a process in which some colloidal material in the vacuolar solution of the cell becomes condensed into a spherical mass, instead of being distributed at random in the water. This spherical mass floats in the vacuolar solution, in which the colloidal particles were formerly dispersed. Its formation is a simple consequence of a gradient in the distribution of cations and correlative distribution of polyphenol oxidase (a copper protein). Although the process of coacervation may to a certain extent be visualized as a separation of phases, the boundary layer is more than the theoretical interphase; it is a precipitation membrane composed of oriented molecules.

The presence of catechol in the central mass of the coacervate is revealed by the brown color developed upon oxidation as well as by its selective absorption of neutral red (Dufrenoy and Reed 1942). Coacervates, therefore, may be defined as centers of high polyphenol oxidase activity with a definite boundary where the oxidizing activity is at its maximum. That boundary is the interphase between the colloidal central mass, in which oxidase activity can be detected, and the surrounding vacuolar liquid in which no such activity can be revealed. The active migration and concentration of basic dyes into the coacervates, and still more conspicuously in the precipitation membrane, are correlated with the aforementioned distribution of polyphenol oxidase. Data to be presented in this paper show that plant cells suffering from certain mineral deficiencies build up accretions wherein the colloidal catechol compound of the vacuolar solution becomes condensed into a concentrated globular mass, and forms a surface film of phospho-lipoids through a molecular orientation at the interphase. This idea is experimentally supported by the fact that catechol reactions may be obtained from the central mass of the globule, and reactions both for fats and phosphorus compounds may be obtained from the surface precipitation membrane (Dufrenoy and Reed, 1942).

It seems appropriate to allude to the relation of the oxidase to permeability and exchange of ions though the phenomenon cannot be here discussed in detail. Raciborski (1898) called attention to the high concentration in the phloem elements of what we now know as indophenol and catechol oxidase systems. Boswell and Whiting (1938), who investigated the oxidase system of potato tubers, concluded that the catechol oxidase is responsible for the major part of the O_2 uptake and of the CO_2 released. The

fundamental importance of the phenol-oxidase for the cell has been emphasized by Hoagland's discovery (1923) that the absorption of solutes is closely dependent upon the energy exchange, and has been studied further by Steward, Stout, and Preston (1940) who showed that respiration of potato disks is partially linked to a respiratory component which was influenced by salts and by oxygen concentration. As the oxidase system plays an essential rôle in cell respiration, it may be expected to play a similar rôle in permeability and water uptake.

TECHNIQUE.—Neutral red and methylene blue are especially useful for *intra vitam* demonstration of catechols in plant cells, though Nile Blue and similar dyes also gave differentiation, part of the dye being absorbed by the central phenolic core and part by the fat in the outer layer. The presence of catechol oxidase was demonstrated by the convergent techniques: (A) post-vital staining and (B) vital staining.

(A) We have used two post-vital staining methods: (1) the classical indophenol blue reaction and (2) the 2-6-dichloro-quinone-chloroimide, a reagent recently introduced as a test for vitamin B_6 which is also very useful as a test for catechol oxidase. The indophenol blue was obtained, as usual, from the neutralized equimolecular mixture of dimethyl paraphenylene diamine and thymol (or alpha naphthol), these mixtures being, for the sake of brevity, designated as thydi or nadi. Upon exposure to the atmospheric oxygen, either of these substances will slowly form phenol blue, but, in the presence of indophenol oxidase, the blue color forms more quickly. With catechol oxidase in the system, however, the formation of indophenol blue is catalyzed indirectly via oxidation of catechol to quinone. Catechol oxidase, being a copper protein, is cyanide sensitive. The 2-6-dichloro-quinone-chloroimide is insoluble in water but soluble in a solution of catechol. The red color, deepening to brown, developing on tissues immersed in a watery suspension of the reagent affords a precise localization of catechol oxidase. This reaction also is cyanide sensitive, as it involves a copper protein. Obviously, the relation of this to metals such as zinc should be investigated.

(B) We have tested the following dyes on free-hand sections of plant material: safranin, thionine, methylene blue, basic fuchsin, neutral red, quinoleine blue (cyanine), rhodamine, and chrysoidin and demonstrated that they accumulated in the coacervates, staining the external membrane more deeply than the central core.

It is assumed that anions (for instance, acid dyes) should be carried from a region of high concentration to one where the concentration is low; and conversely that cations (for instance, basic dyes) should accumulate at the foci of the oxidase system.

We have obtained evidence from cytological observations (Reed and Dufrenoy, 1935) that the blue granules of indophenol blue which form more rapidly at some foci within the vacuolar solution are centers of catechol oxidase activity. Where the colloidal

catechol compound had formed spherical masses, the application of other reagents for oxidase demonstrated that their core is not only the focus for catechol derivatives, but also for catechol oxidase (Dufrenoy and Reed, 1942). Therefore, we should expect a difference of electrical potentials to prevail between the coacervate and the surrounding medium, with a resultant tendency for cations to move into the coacervate through the surrounding membrane. Obviously, this would have a great influence upon the intake of dissolved material by the living cell. On account of the irreversibility of the process the coacervates would trap cations from the vacuolar solution.

The indophenol or catechol oxidase in the presence of the thydi mixture develops a brown color in the phenolic core of the coacervate and a blue color in the lipoidic membrane surrounding it. In this membrane the nascent indophenol blue becomes preferentially dissolved.

The molybdenic reagent, described below, is still more valuable for work on these coacervates. It causes a browning of the inner phenolic core and the formation of blue wherever phosphoric acid is present. Since the enveloping membrane contains phospho-lipoids, it is colored blue by this reagent. It can be applied either to freehand sections of such material, since its strong oxidizing effect produces very efficient fixation, or it can be applied to microtome sections of material previously fixed with good killing agents such as Nemec's or Helly's fluid. Sections treated with the molybdenic reagent may then be stained with haematoxylin or with acid fuchsin and checked against sections of homologous tissues stained directly with those dyes.

The molybdenic reagent for phosphorus compounds is the conventional test for thiamin. It is made as follows:

Add 20.9 cc. of concentrated sulfuric acid to enough water to make up 250 cc. of 3 N solution of sulfuric acid, in which 6.41 g. of ammonium molybdate is dissolved. This constitutes Solution A.

Dissolve 5.75 g. sodium bisulfite in 85 cc. distilled water. Add .5 g. of 1-amino 2-naphthol 4-sulfonic acid and 5 cc. of 20 per cent sodium sulfite solution. Stir the mixture until the sulfonic acid dissolves. This is Solution B.

Slides bearing microtome sections of plant tissues should be placed in a staining jar containing a mixture of 25 cc. of solution A and 5 cc. of solution B. The slides should remain in this for several days until the sections develop a deep blue color. They can then be dehydrated rapidly by washing with 95 per cent alcohol and then mounted in diaphane. As the result of this treatment, nucleoli and prochromosomes, plastids and mitochondria show a blue color. The blue color may be intensified to very dark blue or deep purple by immersing the slide, after it is taken out of the molybdenic solution, for one minute in an aqueous 1 per cent solution of haematoxylin previous to dehydration. However, if one wishes to differentiate mitochondria from plastids, the section can be stained with acid fuchsin and counterstained

with an alcoholic solution of aurantia. Plastids, which then retain a blue-purple color, are beautifully differentiated from mitochondria, which appear bright red.

VACUOLAR INCLUSIONS.—The data which we herewith present have been obtained since the publication of our earlier work and afford additional information concerning the effects of zinc in maintaining the physiological equilibrium of the cell.

Fig. 3. Cells from the post-meristematic region of an affected apricot shoot, in which the nuclei (n) were appressed along the cell walls. Three types of catechol aggregates were found; a fluffy mass (fl) distributed through the entire vacuole, globular precipitates (t) generally at the periphery of the vacuole, and spherical masses (c) enveloped by precipitation membranes, *i.e.*, coacervates.

An important aspect of the phenolic precipitates is shown in cells (fig. 3) from the post meristematic region of an apricot shoot affected with little-leaf. The material had been collected July 29, at a time when growth for the season had practically ceased and when the cells contained a maximum of phenolic materials, as previously described (Reed, 1941). The preparation was made from material fixed in Nemec's solution, and the sections were stained with acid fuchsin followed by methyl green. The nuclei (n) were usually in a parietal position surrounded by a thin film of the abnormally vacuolate cytoplasm. The large central vacuoles contained inclusions of several sorts. The catechol materials in the upper cell had formed a diffuse flocculum (fl) which occupied most of the vacuolar space. They formed numerous spherical precipitates (t) in the cell at the left of figure 3. The catechol materials in the cell at the right formed a coacervated aggregate (c) which contained most of the colloids from the vacuolar solution and was enveloped by an alveolate layer. The vacuole also contained a flocculent precipitate of phenolic material. The diffuse flocculum which the upper cell contained resembled a condition found (Reed, 1938 b) in palisade parenchyma of an apricot leaf which had grown in a culture solution lacking zinc. The cells contained catechol particles which

had separated from the solvent and had only just begun to coalesce.

These three cells (fig. 3) show plainly the import-

ant stages in the formation of the auto-complex coacervate in affected plant cells and emphasize that it starts with the well-known process of syneresis

Fig. 4-7.—Fig. 4. Portion of a transverse section of an apricot leaf affected with zinc deficiency in which the perivascular cells were replete with masses of catechol. In the immediate vicinity of the bundle (x) the catechol masses formed a continuous phase enmeshing a number of vacuoles (t). Other cells contained spherical masses of catechol (c) enveloped by precipitation membranes and may be considered auto-complex coacervates. The plastids (pl) showed abnormalities.—Fig. 5. Cells from the apical region of a vegetative shoot of an affected apricot tree. The catechol material in some vacuoles (v) condensed into globular masses (t); in others it formed an aggregate (c) enveloped by a precipitation membrane. Nucleus (n); mitochondria (m).—Fig. 6. Coacervated material demonstrated by the molybdenic reagent in hypoplastic cells from root of an orange seedling which had grown seven months in a nutrient solution without zinc, (am) amyloplast; (c) coacervates exhibiting vacuolated envelopes of phospho-lipoid material; (m) mitochondria (frequently agglutinated); (n) elongated nucleus.—Fig. 7. Portion of a transverse section of a walnut leaflet, (*Juglans hindsii*), dwarfed and chlorotic by little-leaf. The hypertrophied palisade cells had a definite polarisation of contents, indicated by the position of vacuolar precipitates (t) at one, and nuclei (n) and plastids (pl) at the other pole. The perivascular cells contained globular masses (c) of catechol. Gum (g) and necrotic material (nec) occurred in intercellular spaces.

and ends with a globular mass of catechol surrounded by a layer of phospho-lipoid material floating in the vacuolar sap.

Apricot leaves taken from trees showing little-leaf (zinc deficiency) symptoms show striking derangements, especially in the later part of the growing season (Reed, 1938b). Samples taken during the period of rapid growth in the spring showed no serious derangements due to the lack of zinc. The nature of affected cells is shown by figure 4 which was drawn from a section of an affected leaf collected October 15, at Delhi, California. The material had been fixed in Nemec's solution and double stained with acid fuchsin and methyl green. The derangements were more evident in the perivascular and spongy parenchyma than in the palisade cells although in the latter the plastids were shrunken. There was hypertrophy of many cells, and in the spongy parenchyma (SP) the plastids were surcharged with starch due, apparently, to an inhibited cytase activity. The cells surrounding a xylem element (x) contained catechol material in several forms (t and c) which, as previously shown, is related to the little-leaf condition (cf. Reed, 1938b). The formation of the various aggregates followed some desolvating activity which involved separation and coalescence of catechol compounds. The large vacuolate masses (t) of catecholic material indicate that the shift of equilibrium was so abrupt that it allowed no time for complete separation and, as a result, some droplets of the solvating liquid were held within the aggregate. These masses seem similar in nearly every way to the "tannin vesicles" described by Massee (1895) in pathological cells of orchid leaves. The smaller globular masses (c) of catecholic material indicate a strong activity of catechol oxidase forming + charges on the surface which would attract the basic choline groups of phosphatides and form an enveloping lipoidic layer. Both of these components may be demonstrated with the molybdenic reagent by which the central mass of the coacervated catechol was colored light brown and the outer layer of phosphatide blue. The phosphatide layer of some coacervates like the upper (c) in figure 4 was vacuolated. When sections were double stained with acid fuchsin and methyl green, the core of catechol absorbed the basic methyl green.

We conclude from our investigation of fresh, as well as fixed materials, that the vacuolar solution contains both the oxidizable phenolic compounds and an agent (polyphenol oxidase) which is able to catalyze their oxidation. These phenolic compounds are, nevertheless, protected from oxidation in healthy cells by the presence of hydrogen donors such as ascorbic-dehydroascorbic or the dihydroxymaleic acid systems, even more by the presence of such thiol-containing groups as cystein and glutathione, the latter of which is able to act as a reservoir of hydrogen for the cell. This relationship can be used as the basis for explaining the seasonal variations in the amounts of these bodies previously discussed (Reed, 1938 a and b), since it is known that thiol

compounds and reductases are more abundant in rapidly growing than in mature organs. During the early part of the growing season the leaf cells would have more hydrogen donors and would, therefore, keep the catechol particles randomly distributed throughout the cell vacuole. When growth inhibiting influences such as senescence or nutrient deficiencies intervened, destroying the equilibrium between oxido-reductant factors, the desolvating action already mentioned would produce vacuolar aggregates of the sorts now under discussion (fig. 4).

Skoog (1940) has demonstrated the destructive influence of the oxidases on the growth auxin in plants deprived of zinc, finding that the tissues of such plants exhibited an enhanced oxidative capacity and a corresponding decrease in the growth auxin. It is evident from his work that the abnormally high oxidative capacity of the zinc-deficient plants was responsible for the rapid rate of auxin inactivation. Furthermore, he discovered a phenomenon which has an important bearing on the zinc-catechol-oxidase relationship, namely, an enhanced oxidation of catechol in the extracts of zinc-deficient plants. The abundance of brown compounds often obscured the benzidine test for oxidase.

Another separation of phases was mentioned (Reed, 1938 b) in the lipid-protein complex of the plastids of leaves from severely affected apricot trees after growth had ceased. Droplets of lipid material and vacuolization of the stroma were early stages in the derangements of structure and function which ended in the disappearance of the plastids.

We can now present confirmatory evidence of the rôle of catechol and related phospho-lipoids in the formation of coacervates from a study of cells from the sub-apical region of affected apricot shoots. The effect of the deranged metabolism is clearly seen in the hypertrophy of post-meristematic cells which contained vacuolar aggregates of phenolic materials. Figure 5 shows cells from an affected apricot shoot collected January 24, when the tree was in a state of comparative dormancy. The section had been fixed in Nemec's solution and double stained with acid fuchsin and methyl green. Each vacuole was outlined by pink cytoplasmic strands along which mitochondria (m) showed as many red rods. The catechol in some of the vacuoles formed small globular aggregates (t) which the bichromate of the killing fluid stained yellow. In others the catechol had been coacervated into spherical masses (c), surrounded by precipitation membranes which were darkly stained by virtue of their ability to absorb both acid fuchsin and methyl green from the staining mixture. The cells show the comparative independence of the individual vacuoles and exhibit nuclei compressed into a star shape by the pressure of the adjacent vacuoles.

Further evidence of the two phases in auto-complex coacervates will be seen in figure 6 showing cells of an orange root which had grown in a zinc-deficient culture solution. The section from which

the drawing was made had been treated with the molybdenic reagent and, as a result, showed plainly the vacuolate phospho-lipoid layer surrounding the globules of catechol. The enveloping layer was blue and the central globule light brown after treatment with molybdenic reagent. The brown color of the central globule was due, undoubtedly, to the oxidation of the catechol to a diketone by the reagent.

Fig. 8. Portion of a leaflet of *Juglans regia* affected with little-leaf. The hypertrophied palisade cells were either filled with catechol masses which formed a continuous phase (t), or exhibited varying stages of lysis (ls). The spongy parenchyma cells often contained globular aggregates (c) of catechol. The nuclei (n) were often indistinct.

The idea of two distinct phases in those globules is supported by Caruso's (1939) successful microphotographs of similar inclusions in cells of *Cephalocereus*.

The condition of the cells and the phenolic materials in leaves of the walnut affords important information because in them the polyphenol oxidase is very active. Both the cultivated walnut (*Juglans regia*) and the native (*J. hindsii*) were studied. The affected leaves, which were extremely dwarfed and chlorotic as a result of zinc deficiency, were collected at Delhi, California, on August 12 and fixed in Nemec's killing fluid. These leaves, which are naturally rich in phenolic materials, afford some interesting comparisons with those previously discussed.

The perivascular cells, like those of the peach leaf (Reed, 1938), contained large quantities of phenolic materials and appeared to be severely affected.

The palisade cells of the affected walnut leaves (fig. 7) were hypertrophic, hypoplastic and had a strong tendency to polarization of the contents,

similar to the condition we described in 1935 in affected orange leaves and in 1938 in affected avocado leaves. These conditions were never observed in healthy walnut leaves. The nuclei and plastids of affected cells were at one pole, and vacuolar precipitates were grouped at the opposite pole. Their plastids were small and probably unable to function efficiently. Mitochondria were present but seemed to be in an arrested stage of development. Many of the cells had suffered such extreme lysis that they were practically empty. Necrotic material, which had a strong affinity for hematoxylin, was frequently seen in intercellular spaces (fig. 7, nec), as well as gum.

Catechols were abundant in most cells, occurring either as large masses filling the vacuoles (fig. 8) or as golden brown globules (fig. 7). The conditions resembled the second stage of syneresis shown in figure 3. Globules of catechol which could be regarded as auto-complex coacervates were not readily detected by the staining techniques used. The molybdenic reagent failed to demonstrate any phospho-lipoid materials in association with the catechol globules in the walnut leaf cells. The absence of a desolvant agent like phospho-lipoid would account for a distribution of catechols like that represented in figures 7 and 8, especially in the presence of an active polyphenol oxidase. The absence of phospho-lipoid could result in the diffusion of catechol, sometimes seen in severely affected leaves. Their poverty in other lipoids is reflected in the absence of chlorophyll.

Where both kinds of aggregates occur, as in affected apricot leaves, there may not be enough phospho-lipoid or other desolvant like lecithin to form an auto-complex coacervate of all the material. Klercker also found a precisely similar state of affairs in another tree which is rich in tannin, namely, *Quercus pedunculata*.

The cells in figure 8 afford some interesting contrasts. Cells whose vacuoles were almost completely filled with vacuolated aggregates were adjacent to cells whose vacuoles contained a few globular masses of catechol, leaving the vacuole quite free of other inclusions. From this and other observations one may conclude that proteolytic and oxidative agents sometimes work simultaneously in affected plant cells, but not always.

SUMMARY

Knowledge of the cellular inclusions which seem characteristic of many diseased cells has been advanced by means of new developments in technique which are outlined in the present paper.

These spherical inclusions in the cell vacuoles of zinc deficient plants are formed by a process in which some of the colloidal material in the vacuolar solution of the cell becomes condensed into a spherical mass instead of being distributed at random in the solvent. These aggregates may be formed by a process of coacervation, which may be to a certain extent considered a separation of phases, but they have a boundary layer which is more than the theo-

retical interphase. It is a precipitation membrane composed of oriented molecules.

In the cases we have studied, the mass of the aggregates appears to be made up of catechol. The precipitation membrane or bounding layer is a phospholipoid, identifiable by suitable chemical reagents.

Coacervated aggregates have been found in the vacuoles of hypoplastic cells of leaves and in the post-meristematic cells of growing shoots of apricot trees suffering from little-leaf (zinc deficiency), as well as in the cells of leaves of walnut trees affected with the same malady. Evidence of a pathological

condition in the walnut leaves was also indicated by the escape of necrotic material from the cells and its accumulation in intercellular spaces, coupled with the formation of gum in intercellular spaces adjoining severely affected cells.

HORMODENDRUM RESINAE (LINDAU), AN INHABITANT OF WOOD IMPREGNATED WITH CREOSOTE AND COAL TAR ¹

C. M. Christensen, F. H. Kaufert, H. Schmitz and J. L. Allison

COAL TAR products, especially creosote, have been used for more than a hundred years to protect wood from attack by fungi, insects, and other organisms, and the best evidence of their preservative value is the long service given by wood impregnated with them. Some of the compounds contained in these preservatives are very toxic to most fungi, and since each cubic foot of wood impregnated with them contains 8 to 20 pounds, or 1 to 2½ gallons, of preservative, such wood scarcely would be suspected of har-

Fig. 1. Young sporophores of *H. resinae*. The three at the left are 48 hours old, the larger one at the right 72 hours old. $\times 900$.

boring living organisms. A brown mold has been observed occasionally by us and others² on small pieces of impregnated wood (usually from ties or poles that had been in service for some time) placed in moist chambers or on agar during routine tests of such wood for resistance to decay. Because of the known toxicity of these preservatives to microorganisms in general, this sporadic appearance of a fungus on treated wood was more or less disregarded as a laboratory phenomenon. Our present investigations prove that this mold is a common, if not an almost universal, inhabitant of wood treated with coal tar products, including creosote.

In the fall of 1939, several tie plugs overgrown with this brown mold were received from Dr. Herman von Schrenk of St. Louis. These plugs had been impregnated with coal tar early in the summer of 1939, packed tightly in square bundles, and stored in a shed where the humidity was high. The general appearance of the fungus on the tie plugs is shown in figure 2A.

¹ Received for publication April 3, 1942.

Paper No. 1989 of the Scientific Journal Series, Minnesota Agricultural Experiment Station.

IDENTITY AND DESCRIPTION OF THE FUNGUS.—Several pure cultures of the fungus were made, and one was sent to Dr. Johanna Westerdijk, director of the Centraalbureau voor Schimmeldkulture, Baarn, Holland, for identification. The culture was there compared with the available species of *Cladosporium* and *Hormodendrum*, and was found to differ from them, the opinion being expressed that it might be an unknown species of *Cladosporium* (*Hormodendron* or *Hormodendrum*).

Cultures of the fungus on the usual artificial media, such as malt and potato dextrose agars, are white when very young, but within a few days become dark olive brown or nearly black, due to a dark pigment in the walls of the hyphae. The mycelium is appressed, but the great number of spores give the cultures a powdery appearance. Numerous black, wrinkled sclerotia from 0.1 to 2 mm. in diameter are formed on the surface of and within the agar of six-week- to two-month-old cultures.

Sporophores and spores are produced in cultures twenty-four hours old, typical ones being illustrated in figure 1. As these become older, the spore masses form rather dense heads, varying from spherical to conical or cylindrical, at the tips of the sporophores. Each head contains hundreds of conidia.

The spores are pale olive brown and vary in shape from spherical to elongate oval. Cultures from the tie plugs were grown on balsam fir wood, filter paper, leaves, and prunes; and spores produced by the fungus on these media were mounted in a drop of cool agar and measured with the aid of an ocular screw micrometer and an oil immersion lens. The average length of 100 spores was 4.5 microns, the range being 3.2 to 9 microns. The average length of the first 50 measured differed only 0.5 micron from that of the second 50. One hundred spores from a culture isolated from a butt-treated western red cedar pole in Wilmington, Delaware, were similarly measured and averaged 5.1 microns in length. The length of spores from other cultures of the fungus obtained from other areas and grown on several different media did not differ significantly from the above averages.

The fungus undoubtedly is a species of *Hormodendrum* or *Cladosporium*. A few words concerning the genera in question may be desirable. Lindau, in Rabenhorst's *Kryptogamen Flora*, Vol. 1, Pt. 8, and also in Engler and Prantl's *Die Natürlichen Pflanzenfamilien*, and Saccardo in *Sylloge Fungorum*, merely repeat Bonorden's original description of *Hormodendrum*, made in 1851, which is: "Sterile hyphae procumbent, branched, septate. Conidiophores upright, septate, brown, repeatedly branched or only a little branched. Conidial chains acrogenous, often comprising the entire branch down to the stem. Conidia spherical or egg shaped, olive green or brown, one celled." The original description of *Cladosporium* is almost identical, differing chiefly

in that *Cladosporium* was said to have two- or several-cell spores.

That portion of Die Natürlichen Pflanzenfamilien dealing with these two genera was written by Lindau in 1889 (according to his statement in Thesaurus Litorarum Mycologicae, vol. 1, p. 862). The similar portion in Rabenhorst's Kryptogamen Flora was written by Lindau in 1906. In the earlier work he states that the spores of *Hormodendrum* have one cell, and those of *Cladosporium* two cells. In the later work he is less positive of this distinction, and to his description of *Cladosporium* he appends the remark that the genus is exceedingly variable and difficult to describe, and that he would prefer to consider the multicelled nature of the conidia, and the ability of the conidia to bud as characteristic of *Cladosporium*. In spite of this, three of the 63 species of *Cladosporium* he describes in Rabenhorst's Kryptogamen Flora are said to produce one-celled spores only.

Among the species of *Hormodendrum* that Lindau describes in the Kryptogamen Flora is a new one, *H. resiniae* Lindau, found growing on resin of *Picea excelsa* in the Sachsenwald near Hamburg. In the short description of this species he states: "The conidia are in short chains, which are either sparsely distributed along the stem of the main conidiophore or united in heads. Conidia ellipsoid-spindle shaped, bluntly pointed at both ends, greenish brown, transparent, 5.5 to 7 microns long, 3.5 to 4.5 microns thick." He further states that the conidiophores show the typical *Hormodendrum* form, somewhat as in *H. hordei*, an illustration of which is given. Of all the species of *Hormodendrum* and *Cladosporium* he describes, the above *H. resiniae* most closely agrees with our fungus. Its growth on resin may be significant also, as will be shown later.

Since Lindau's time, species seemingly intermediate between *Hormodendrum* and *Cladosporium* have been described, and it has been suggested that the two genera be united. Our fungus certainly does not form two-celled spores, even in cultures a year or more old; if this be a legitimate generic character, we are justified in considering it a species of *Hormodendrum*. Since it conforms rather closely to the description of *H. resiniae* Lindau, we have tentatively referred it to this species.

OCCURRENCE OF *H. RESINAE* IN NATURE.—Earlier observations by the writers that *H. resiniae* was present in coal tar and creosote-treated wood obtained from a number of localities, stimulated a more detailed study of its occurrence in treated wood and its general distribution in nature.

Isolations from wood impregnated with coal tars and creosotes.—Most of the creosoted wood sampled in this study was from poles or ties, these products making up a large part of the material treated with creosote and coal tar. Samples were taken from creosoted telephone poles and railroad ties in service, or recently removed from service. The fungus was isolated and grown on malt agar and malt agar containing 0.24 to 1 per cent coal tar creosote (the latter hereafter referred to as agar-creosote medium).

Such concentrations of creosote in malt agar prevent the growth of most of the common contaminants but permit the growth of *H. resiniae*. That *H. resiniae* can grow on malt agar containing higher concentrations of creosote will be shown later.

Samples were taken near the ground line from twenty-nine creosoted poles in Minnesota, Wisconsin, Pennsylvania, and Delaware; and *H. resiniae*

Fig. 2.—A (above). Tie plugs impregnated with coal tar. The lower one is overgrown with *H. resiniae*.—B (lower right). Two increment borings from a pressure treated southern pine pole cultured on agar-creosote medium. *H. resiniae* was obtained from all four pieces of each boring.—C (lower left). An increment boring from a butt treated western red cedar pole, cultured on agar-creosote medium. *H. resiniae* has grown out of only the dark, creosoted portion.

was isolated from twenty-seven of them. It was likewise isolated from six of the eight creosoted ties sampled in Minnesota, and from all of the eleven ties from Ohio, from all of the four ties sampled from Louisiana, three from the State of Washington, and from ties sampled from Missouri and Indiana. The fungus was found in both butt-treated cedar poles and full-length pressure-impregnated southern pine poles. The ties from which it was isolated include such species as jack pine, southern pine, red oak, birch, and red gum. Other creosoted material from which the fungus was isolated includes: a Douglas fir cross arm impregnated with creosote and stored at the treating plant for three months, southern pine fence posts pressure treated with creosote and stored in a basement room for several years, several creosoted southern pine fence posts in service for seventeen years in Iowa, and the tie plugs referred to above.

Service records were available for most of the materials sampled. These records revealed that *H. resinae* was obtained from almost every creosoted pole in service for two years or more. The recovery of *H. resinae* from the cross arm and from posts that never had been in service may be accounted for by their storage out-of-doors or in a room sufficiently humid to permit the fungus to grow in the treated wood. The fact that samples of freshly creosoted wood, placed in a humid chamber and inoculated with a spore suspension of *H. resinae*, will be overgrown rapidly by the fungus is added evidence that length of service has less bearing on the prevalence of the fungus than such factors as moisture and presence of inoculum.

The samples were taken from telephone poles by means of an increment borer, each boring being 2 to 3 inches long. In the case of western red cedar, which is impregnated by steeping the lower portion of the pole in an open tank of alternately hot and cold creosote, the boring extended through the creosoted wood and included an inch or more of nontreated wood. Most of the latter borings were cultured by breaking them into several pieces, the pieces then being placed on agar in a Petri dish or each piece being put on agar in a separate test tube. *H. resinae* grew out of almost every portion of each boring (fig. 2B), indicating that it extended deep into the wood and was not merely on the surface. When the isolations were made on malt agar containing no creosote, usually only *H. resinae* grew out of the creosoted wood and no organisms grew from the inner, nontreated portion. In a few cases an as yet unidentified fungus grew from the inner, nontreated portion.

It would of course be theoretically possible for spores of *H. resinae* to be carried in from the surface of the pole by the increment borer when the sample was taken. Were this the case, however, one would almost certainly obtain it from the noncreosoted inner portion of the boring. Therefore, it seems fairly certain that the fungus grows in as far as the creosote extends, and no farther. Other organisms sometimes are present in the nontreated inner portion of the wood and might prevent the growth of *H. resinae*. The inability of *H. resinae* to compete with common molds on nontreated wood will be discussed below.

Most of the creosoted ties were sampled by chopping from each a block about six inches long and extending in to the center of the tie. The surfaces of each block were flamed, then the block was split lengthwise to expose a surface extending from the outside of the tie into the center. Usually the creosote did not extend more than two inches in from the outside. Small pieces of wood were taken adjacent to one another across both the creosoted and noncreosoted areas. In almost every case *H. resinae* grew out from every piece taken from the creosoted portion but from few or none of those taken from the noncreosoted portion. Most of these isolations from ties were made on malt agar to which no creosote had

been added, but in only a very few cases did any organism other than *H. resinae* grow out of either the creosoted or noncreosoted wood. This is additional evidence that the fungus is a regular inhabitant of creosoted wood but does not grow readily on noncreosoted wood in nature. Further evidence will be presented that the fungus not only tolerates coal tar or creosote but may derive nourishment from it.

The results of these studies indicate that *H. resinae* must be a very common and general inhabitant of wood impregnated with coal tar and coal tar creosote throughout much of the United States, and is not limited to one product or one region.

Possible natural habitat and sources of inoculum.—It seems at least probable that any organism, such as *H. resinae*, which grows in wood impregnated with coal tar or creosote, which are man-made products of relatively recent origin, must have been on the scene long before these products appeared; therefore, it was of some interest to look for a natural source of inoculum.

Creosoted wood blocks, and agar to which sufficient creosote had been added to prevent the growth of most organisms except *H. resinae*, were exposed repeatedly in the laboratory and out-of-doors for as much as a week at a time, and then incubated for weeks or months in the laboratory, but not a single culture of *H. resinae* was obtained. While this at least indicates that few spores were present in the air at the time and place of the exposures, it does not exclude the possibility of the spores being predominantly air borne and being present in abundance during certain times and at certain places.

Plant refuse was placed on creosote-agar in Petri dishes and incubated without obtaining the fungus. Numerous isolations from greenhouse soil on the same agar-creosote medium yielded only one culture of *H. resinae*. Soil samples were taken from nine different locations within an eight-mile radius of the University Farm, St. Paul, Minnesota, including cultivated and uncultivated land, one of them from within a few yards of a large creosoting plant, and cultured on agar-creosote medium. *H. resinae* was not obtained from any of these.

Samples of asphalt street pavement were taken from five different places and cultured on agar-creosote medium and also on creosoted wood blocks. Three of these yielded *H. resinae*, but in no great abundance. In all others the asphalt was slowly overgrown by a fungus, as yet unidentified, mentioned above as being isolated from a few samples of creosoted wood. This same organism grew out from every part of almost every soil sample on the agar-creosote medium, although it grew but poorly on this medium.

Resinous bark and twigs from fifteen blue spruce trees affected with *Cytospora* canker were cultured on agar-creosote medium and also on creosoted wood blocks. *H. resinae* grew out from thirteen of these, and typically grew out of the entire bark surface, not only from isolated spots. It is possible that this and other resinous woods form one of the natural

habitats of *H. resinae*, but the evidence at present is not sufficient to make this more than a possibility.

Creosoted wood blocks in jars that were opened frequently, and plates of agar-creosote medium, were regularly maintained as controls in all these isolation experiments, but in no case has *H. resinae* or any other organism appeared on them.

THE BIOLOGY OF *H. RESINAE*.—The studies described below were made to determine some of the factors influencing the growth of *H. resinae*, its tolerance to coal tar products, and whether it might be able to utilize certain coal tar products.

Effect of temperature.—Petri dishes containing 5 per cent malt agar were inoculated with a spore suspension of *H. resinae*, kept at room temperature (20 to 25°C.) for three days, then placed in incubators maintained at 5, 10, 15, 20, 25, 30, and 40°C. Ten days later the colonies at 5° were 0.5 cm., those at 30° were 3.77 cm. and those at 40° were 1.37 cm. in diameter. Compared with fungi in general *H. resinae* has a rather high optimum and a wide temperature range. Neither the minimum nor maximum temperatures were reached in this experiment.

Effect of pH.—Yield of the fungus, as measured by weight of mycelial mats, from triplicate flasks of Pope's medium adjusted to twelve different pH concentrations from 3.0 to 10.5 varied so much as to preclude a definite statement as to minimum, maximum, and optimum pH concentration for growth. The weight of mycelium produced in fourteen days was almost the same at pH 3 as at pH 8, lower at pH 9.6 and higher from 3.5 to 8.0. At the end of the experiment, the media at all but the lower and two upper pH concentrations had a pH of 7.0. Like many other microorganisms, *H. resinae* appears to grow over a rather wide pH range, and has the ability to alter the original pH of the medium.

Effect of inorganic toxicants.—The resistance of *H. resinae* to CuSO_4 , ZnCl_2 , and AsO_3 , respectively, was determined by adding these compounds to malt solution (25 grams of malt extract in 1,000 cc. of water), in various concentrations. The culture flasks

were inoculated with spore suspensions of the fungus. Approximately 150 parts of copper sulphate and 380 parts of zinc chloride per million of malt agar were required to inhibit growth. Wood destroying fungi, such as *Lenzites trabea*, Madison 517, *Trametes serialis*, and *Lentinus lepideus*, have a far higher tolerance to these common inorganic toxicants, and the killing concentrations as given by Bateman (1937) are many times as high as those totally inhibiting the growth of *H. resinae*. In case of AsO_3 , 1,200 parts of arsenic trioxide per million did not decrease the growth of the fungus much over that of the controls. It would appear from these results that *H. resinae* is fairly resistant to arsenic. However, there are many fungi tolerant to high concentrations of arsenic, among them *Lenzites trabea* and a number of common molds, Bateman (1937) and Kaufert and Schmitz (1937).

It would appear from these results, that *H. resinae* is not an unusual organism in its resistance to some of the common inorganic toxicants used as wood preservatives. Judging from these results, one would not expect to isolate *H. resinae* from wood treated with these inorganics more often than some of the other organisms given above.

Effect of coal tar products.—The tolerance of *H. resinae* to coal tar and creosote was determined by the standard agar-plate method, and by treating wood, filter paper, and glass beads or slides with creosote and coal tar and inoculating the treated materials with spore suspensions of the fungus.

Agar tests.—These tests were made by the procedure described by Schmitz, *et al.* (1930). Characteristics of the creosotes and coal tars used in these studies are shown in table 1.

These creosotes and coal tars are representative samples of materials used by the wood preserving industry, at the time the samples were obtained. The results of toxicity tests with creosotes A and B are shown in table 2.

A further test with creosote C and coal tars A and B, in which the agar-creosote or agar-coal tar mix-

tures were placed in jars with loosely fitting screw caps and were inoculated with spore suspensions of *H. resinae* every seven days for three months, revealed that the organism would grow on agar containing as much as 10.0 per cent creosote or coal tar. The conditions in these later tests were very different from those in the tests summarized in table 2 because there was opportunity for loss of some of the lower boiling fractions, and presence of viable inoculum was assured by repeated inoculations.

The extreme tolerance of *H. resinae* to coal tar products is best illustrated by comparing the results reported above with the results obtained in parallel tests with creosotes A and B and several common wood-destroying fungi. Both creosotes killed *Coniophora cerebella* at a concentration of 0.05 per cent, *Madison 517* at a concentration of 0.3 per cent, *Lenzites sepiaria* at 0.3 per cent, and *Trametes serialis* at 0.2 per cent.

Wood tests.—Aspen blocks 1 by 1 by 1½ inch were impregnated with creosote C and coal tars A and B (see table 1 for characteristics of these oils) by first subjecting the blocks to vacuum treatment and then adding the warmed coal tar and creosote without breaking the vacuum. Retentions in the blocks varied from five to twenty pounds per cubic foot. After impregnation, one-half the blocks treated with each of the above oils were heated to 100°C. for eighteen hours. This treatment was considered sufficient to remove most of the volatile components of these oils. Twenty blocks comprised each set. Each set of twenty blocks was put in a separate humid chamber and atomized with spores of *H. resinae* suspended in sterile distilled water.

Mycelial wefts became visible on some of the blocks three days after inoculation, and three months after inoculation all the blocks treated with coal tar were covered with abundantly sporulating mycelium. Mycelium and spores were less abundant on the blocks treated with creosote but were sufficient to give the blocks a definite moldy appearance.

Blocks cut from recently creosoted Douglas fir cross arms, cedar poles, and southern pine posts and placed in humid chambers soon became covered with mycelium of *H. resinae*. It was not necessary to

inoculate these samples of creosoted wood cut from material that had been treated for some time, the surface of the material apparently having sufficient inoculum from natural contamination from the air or other sources.

The growth of *H. resinae* on wood freshly treated with creosote or coal tar and its inhibition in agar plate tests by 5.0 and 10.0 per cent concentrations of the same materials, emphasizes again the great differences between agar and wood as test media.

Filter paper tests.—Cellulose filter papers were sterilized, one edge dipped in samples of coal tars A and B and creosote C, placed in jars and atomized with a spore suspension of *H. resinae*. The fungus grew and fruited readily and abundantly on the portion of the filter paper soaked in tar, less readily and less abundantly on that dipped in creosote, and sparsely or in patches, or in many cases not at all on the filter paper alone.

Glass slide and bead tests.—Clean glass slides, and glass beads cleaned with concentrated sulphuric acid, washed thoroughly with distilled water, and heated to a red heat to remove all organic matter, were dipped in samples of coal tar A and B and creosote C respectively, atomized with a spore suspension of *H. resinae*, and kept in tightly closed bottles. The spores germinated in both tar and creosote, grew and fruited fairly well on the tar and grew and fruited very sparsely on the creosote. On both, the growth was so sparse that microscopic examination was necessary to find it.

The results of these experiments indicate that *H. resinae* derives some nourishment from the constituents of typical coal tars and creosotes used as wood preservatives. The consistently better growth and sporulation on coal tar as compared with creosote, whether on glass beads, impregnated filter paper, or impregnated wood, obviously suggest that either coal tar contains more substances which the fungus can utilize as food or the creosote contains more compounds toxic to it. Very probably it is partly both. Experiments now are under way to determine this.

Ability of *H. resinae* to compete with other organisms on wood and in soil.—The common occurrence of *H. resinae* in creosoted wood in service, and our failure to obtain it from untreated wood, soil, and other materials commonly inhabited by saprophytic fungi, suggested that possibly it could not compete in ordinary media with common molds and bacteria, and grew in creosoted wood not only because of its high tolerance to coal tar products but because competition with other organisms did not exist in this medium. The ability of *H. resinae* to compete with other fungi on untreated wood was studied.

Strips of sapwood 1 by 2 by 16 inches were cut from a fresh red pine log, and one-half of these strips were sterilized and placed in screw-capped jars, the other half placed in jars without being sterilized. One-half of each series were inoculated with a spore suspension of *H. resinae* alone and the other half inoculated with a mixture of *H. resinae* plus *Peni-*

cillium, *Aspergillus*, and *Trichoderma*. The wood strips were examined at intervals of two weeks, for a period of six weeks, the jars being opened during each examination. The results were:

A. Wood sterilized and inoculated with *H. resiniae* alone. At the first examination the wood was totally covered with a heavy growth of *H. resiniae*; at the second examination other molds were starting to come in and at the end of the test *H. resiniae* was no longer visible. A species of *Penicillium* covered most of the surface of the blocks at the end of test and probably came in when the jars were opened for the first and second examinations.

B. Wood not sterilized, inoculated with *H. resiniae* alone. A trace of *H. resiniae* was visible on the lower ends of the pieces at the first examination but this rapidly disappeared, and at the end of the test the wood was uniformly covered with *Penicillium* and *Aspergillus*.

C. Wood sterilized and inoculated with *H. resiniae* plus other molds. At the first examination a trace of *H. resiniae* was present but as in B this rapidly disappeared and other molds predominated.

D. Wood not sterilized, and inoculated with *H. resiniae* plus other molds. No *H. resiniae* was found at the first examination, the surface of the wood being uniformly covered with the other molds used.

To summarize, then, *H. resiniae* grew luxuriantly on wood that had been sterilized to eliminate all competitive fungi, but it could not compete with the other fungi used in this experiment, and even after having become established was quickly overgrown by these other molds. After the third examination, the blocks were taken out of the jars and stored outside where the temperatures were below freezing most of the time. About a month later eight of the blocks were selected, spores washed from the surface with distilled water, and the spore suspensions cultured on agar-creosote medium. A few colonies of *H. resiniae* were obtained on several of the dishes, indicating that the organism still survived but that viable spores were not present in any abundance.

To determine whether *H. resiniae* could compete with other organisms in the soil, the following simple tests were made:

Approximately 100 cc. greenhouse soil were put in ten 250 cc. Erlenmeyer flasks, and five of them were kept for one hour in an autoclave at twenty lbs. steam pressure. Three of each series of five flasks were inoculated in a small area at one side with two drops of spore suspension of *H. resiniae*, and two of each were inoculated over the entire surface with a similar spore suspension, to determine if the fungus could survive and grow in sterilized and unsterilized soil. The flasks were kept at room temperature in the laboratory.

After three weeks isolations were made from three places in each flask of non-sterile soil which had been inoculated at one side: (1) opposite the point of inoculation; (2) in the center of the flask; (3) at the point inoculation. In each case from $\frac{1}{10}$ to $\frac{1}{3}$

cc. of soil was scattered over the surface of a Petri plate containing agar-creosote medium. *H. resiniae* was isolated in only one out of the nine attempts, and in that case from the point of inoculation. It was isolated from both of the samples inoculated all over, but only a few colonies appeared. It grew visibly on the surface of the sterilized soil in all cases and was reisolated from every sample.

H. resiniae was, however, isolated from each of five samples of soil from near the base of five different creosoted poles, but one would expect a fairly heavy concentration of spores there. It was also isolated from soil and duff beneath young tamarack trees in an arboretum and from soil beneath a dead spruce tree, the bark of which was covered with exuded resin. It seems unlikely that *H. resiniae* is a common soil inhabitant; at least the present evidence indicates that it is unable to survive long in competition with the multitude of organisms in some soils, and in those few instances when it was isolated from the soil it is likely that the soil was contaminated by spores from nearby creosoted or resinous wood.

Effect of H. resiniae on wood.—The fact that *H. resiniae* was found so abundantly in wood impregnated with coal tar and creosote suggested that it might have some effect on the strength of the wood. That this effect probably would be small was indicated by the excellent condition of all of the creosoted wood samples from which the organism was isolated. These observations and the resistance of creosoted wood to mechanical wear even after 30 to 40 years of service are sufficient proof that *H. resiniae* could not appreciably affect the strength of such wood.

To obtain some information on this point, small sapwood blocks of longleaf pine, shortleaf pine, Ponderosa pine, soft maple, black gum, paper birch, and aspen were inoculated with this fungus and incubated for ten months. Most of these woods are known to be very susceptible to the action of wood destroying fungi, but in no case was there any evidence that *H. resiniae* was capable of causing loss in weight or other visible changes in the physical properties or appearance of the test blocks, other than a slight staining of the surface. In all cases the fungus grew over the surface of the test blocks and spores were produced in profusion.

Further tests are necessary to determine accurately the effects of this fungus on wood, because loss in weight, though good indication of loss in strength for wood attacked by wood-rotting fungi, is less strikingly correlated with loss in strength where other wood inhabiting fungi are concerned. Chapman and Scheffer (1940), working with blue staining fungi in southern pine wood, found that very small specific gravity changes were often accompanied by large changes in strength, particularly in toughness, which was greatly reduced by many fungi causing blue stain.

Associated with other organisms in creosoted wood.—When the agar-creosote medium was ex-

posed to air in an attempt to isolate *H. resinae*, occasional colonies of a bacterium were obtained. This same bacterium was isolated in considerable abundance on agar-creosote medium from plant refuse and from all soil samples. In isolations from soil, some plates were entirely overgrown with this bacterium for some time before *H. resinae* appeared. It also was isolated from many of the samples of creosoted wood from poles and ties and appears to be almost as common an inhabitant of such material as *H. resinae*. Like the white, as yet unidentified, fungus previously mentioned, the bacterium was often obtained from deep in the wood. It also was isolated from all asphalt samples cultured. It seems doubtful if it has any intimate biological connection with *H. resinae*, but its significance, if any, is not yet known. It is mentioned as another organism more or less regularly inhabiting creosoted wood.

DISCUSSION.—Although wood impregnated with coal tar or creosote is highly resistant to the attack of insects and organisms that deteriorate untreated wood, it is by no means free from microorganisms. That it is a fairly favorable habitat for the growth of *H. resinae* and an unidentified bacterium appears evident. The fact that the organisms here reported grow commonly in such treated products is somewhat surprising but certainly tends in no way to reflect on the proven value of creosote as a wood preservative. There is no evidence that *H. resinae* or the unidentified bacterium tend in any way to reduce the preservative value of these compounds, nor does it seem likely that they affect any of the intrinsic properties of the wood that they inhabit. They are, so to speak, casual interlopers who find among the multitudinous compounds contained in creosote or coal tar some materials that they can utilize; and, in addition, they must possess an unusually high resistance to the numerous highly toxic compounds that they cannot utilize. It seems unlikely that they "prefer" such a medium for growth, if one may use so teleologic a term, but that they do grow commonly in creosoted wood scarcely can be doubted in light of evidence here reported.

SUMMARY

A fungus tentatively identified as *Hormodendrum resinae* was isolated from a variety of creosoted wood products collected over a large territory in the United States. *H. resinae* appears to be a universal inhabitant of creosote and coal tar treated wood in service.

It is unlikely that this fungus is a common saprophyte in soil, on untreated wood, or plant refuse, since it is unable to survive well in competition with common molds. Resinous bark and wood possibly formed the original source of inoculum although other sources, as yet undiscovered, may exist.

H. resinae not only tolerates a far higher concentration of creosote and coal tar than other fungi but is able to grow and reproduce with no other source of nourishment than occurs in these compounds. It appears to be capable of metabolizing some of the components of creosote and coal tar.

H. resinae is no more resistant to inorganic toxicants than a number of other fungi.

It appears to have no effect on the strength of the wood it infects.

An unidentified bacterium was isolated from a large majority of the samples of creosoted wood from which isolations were made.

DORMANCY AND APICAL DOMINANCE IN POTATO TUBERS ¹

H. David Michener

IT IS well known that potato tubers have a rest period lasting for two or three months after harvest, during which they will not sprout even if placed in a favorable environment. Denny and Miller (1938), Stuart and Milstead (1934), and others have shown that treatments with ethylene chlorohydrin break this rest period and produce growth in ten to twenty days after treatment. It was also shown by Michener (1941) that ethylene chlorohydrin treatments ac-

celerate germination not only in completely dormant tubers but in ones which are starting to germinate after having passed through their rest period and in ones which are starting to germinate as a result of a previous ethylene chlorohydrin treatment.

Werner (1931) has shown that ethylene chlorohydrin treatments also increase the number of buds or eyes which grow into stems. This has been confirmed by Michener (1941), who showed that the increased number of stems caused by treatment may result in an increase in yield, at least under certain conditions. As shown in table 1, the increase in the number of stems per tuber is greatest if the tubers are starting to grow when treated, either as a result

^a Summarized from data presented by Michener (1941).^b When the second treatment was made the buds were about 1 mm. long.

of a previous treatment with chlorohydrin or because they have completed their rest period (see fig. 1).

In the untreated tubers, growth occurs only in buds which are near the apex of the tuber (Apple-

man, 1918). This may be due to dominance of the apical buds over lateral buds, or it may be because the apical buds have a shorter rest period and, therefore grow first. In the former case apical and lateral

Fig. 1. A. Untreated dormant Bliss Triumph tubers, thirty-one days after harvest. B. Similar tubers to A, treated for two days with 0.9 cc. ethylene chlorohydrin per kg. of tubers. Treatment made fourteen days before photograph was taken. Most of the buds show growth. C. Untreated Bliss Triumph tubers, about fifty days after harvest. Most of the eyes which have grown are near the apices of the tubers. D. Similar tubers to C, treated for 1½ days with 1.0 cc. ethylene chlorohydrin per kg. of tubers. Treatment made twenty-one days before photograph. Buds are larger than in C, and more have grown than in C. The position of the apex of the tuber may be determined by the more or less compact group of buds around it. For example, in group C the tuber in the lower right hand corner has its apical end towards the camera while the one in the lower left hand corner is turned on its side with the apex hidden. Most of these tubers have the apex turned towards the camera.

buds should grow synchronously if they are separated by cutting the tuber; but in the latter case the apical buds should grow sooner, even if separated from the lateral buds.

The relative vigor of apical and basal seed pieces has been studied by several workers, including Stuart, Edmundson, Lombard, and Dewey (1927) and Westover (1930), who also review earlier work on the subject. Although earlier authors disagreed in some cases, the authors mentioned were unable to find any constant difference in yield between plants grown from apical and those grown from basal seed pieces.

Appleman (1918) cut potato tubers transversely in two and found that the basal half grew sooner than the apical half. However, the apical buds grew in the apical halves of the tubers, while in the basal halves the buds which grew were usually close to the cut surface.

Since Thornton (1939) states that removal of tissue near a bud causes that bud to grow in advance of others on the same tuber, it is possible that the outcome of Appleman's experiments was affected by the proximity of the lateral buds to the cut surfaces.

In the present paper it is shown that apical and lateral seed pieces germinate at approximately the same time if they are cut out of the tuber in such a way that apical and lateral buds each bear the same spacial relationship to the cut surfaces around them. It is concluded that the buds in the apical region of the tuber (hereafter referred to as apical buds) do inhibit growth of the lateral buds. This inhibition is shown to be brought about by auxin produced in the apical buds.

It is also shown that ethylene chlorohydrin treatments cause destruction of a large proportion of the auxin in the tuber. As the dominance of the apical buds depends on auxin which they produce, it is lost when the auxin is destroyed. The lateral buds are then able to grow. The possibility is also considered that this destruction of auxin is also responsible for the breaking of dormancy after ethylene chlorohydrin treatment.

METHODS.—The ethylene chlorohydrin treatments were carried out by the method previously recommended by Michener (1941), in which the tubers are placed in a closed chamber containing a dish of liquid ethylene chlorohydrin, which evaporates and is taken up by the tubers. For each kg. of potatoes 1.0 cc. of ethylene chlorohydrin was used, and the treatments were made at room temperature and lasted for three days, except where otherwise mentioned.

The varieties used were Bliss Triumph, White Rose, and Russet. All appeared to behave similarly in experiments concerned with dormancy and reaction to ethylene chlorohydrin treatment.

For auxin extractions (by the method of van Overbeek, 1938) cubes of fresh potato tissue having a volume of about 1 cc. were placed over night in peroxide-free ether in a refrigerator. After the ether was poured off, the tissue was rinsed with a second

portion of peroxide-free ether which was then added to the first. The ether was evaporated down to about 1 cc., added to a vial containing a measured amount of 1.5 per cent agar, and evaporated, leaving the auxin in the agar. The auxin was then determined by the standard *Avena* test.

From appropriate control tests it was possible to calculate the concentration of auxin (as indoleacetic acid) in each sample of tissue by the method suggested by van Overbeek and Bonner (1937). In the experiments in which this calculation was not made, the auxin was taken up in a volume of agar which was proportional to the weight of the sample. In these cases the curvature obtained in the *Avena* test, therefore, represents the concentration of auxin in the potato tissue, within any single experiment.

When the potato cubes were sliced (about 2 mm. thick) and dried before extraction, less auxin was obtained. When they were similarly sliced and extracted without drying the amount of auxin obtained was slightly less than when the tissue was extracted without being sliced.

For each extraction, 50 to 100 grams of tissue was used. Except where otherwise mentioned, this was a composite sample taken from five to fourteen tubers.

In order to determine how much of the auxin was extracted by this method, potato cubes were placed in ether for two hours, removed to a second, third, and fourth portion, each for two hours, and a fifth for eight hours. The first experiment was carried no farther, while in a second the potato cubes were placed in a sixth portion of ether for two hours and in a seventh for twenty-four hours. All ether portions were found to contain auxin, showing that auxin continued to diffuse out of the potato cubes. In the first experiment (with Russet tubers) the rate of diffusion out of the tissue fell to about 12 per cent of its initial value while in the second (with White Rose tubers) the rate only fell slightly during the experiment. The reason for this difference is not known. However, within each one of the experiments described below, all tubers were of the same variety, from the same source, and similar in size and appearance. Hence, it is believed that, within any one experiment, results of different auxin extractions are comparable.

EXPERIMENTAL RESULTS.—*Interrelationship between buds in dormant tubers.*—In order to determine whether the apical buds actually inhibit growth in the lateral buds, or whether they merely have a shorter rest period, a number of tubers were prepared as follows: Two cubes of tissue, about 1 cm. on a side, were removed from each tuber in such a way that one contained an apical bud and one contained a lateral bud, each with the skin surrounding it. At the start of the experiment the buds were about 0.1 mm. in length. These were placed for a day in strongly aerated water, as previous experiments had shown that potato pieces of this size grew better after such treatment. After this they were placed on wet filter paper in a moist chamber. When this ex-

^a As determined by χ^2 test.

periment was done with Bliss Triumph tubers, which were completely dormant at the start of the experiment, there was no difference between the growth of the apical eyes and that of the lateral eyes after thirty days. After forty-three days, the lateral eyes had grown slightly more (table 2). The same experiment was done with Russet potatoes, in which the apical buds were showing slight growth (less than 0.5 mm.). As was expected in this case, the apical buds grew faster than the lateral buds. Similar experiments with potatoes which had first been treated with ethylene chlorohydrin gave the same result except that growth began sooner.

As has been pointed out previously, cutting the tubers causes the buds to grow sooner than if they were not cut. As all of the pieces were cut in the same way, however, this effect should not influence the outcome of the experiment.

There is thus an obvious similarity between the potato tuber, in which lateral buds grow if separated from the terminal buds, and the pea seedling, in which lateral buds grow if the terminal bud is removed. In the pea seedling, auxin produced by the terminal bud inhibits growth of the lateral buds (Thimann, 1939). It may also be true in the potato that the apical buds produce auxin which inhibits growth in lateral buds. The following experiments were designed to test this hypothesis.

In order to study the distribution of auxin in the potato, tubers were divided into three parts: apex, sides, and center. The apex consisted of about one-sixth of the potato at the apical end. The side was a broad ring of tissue cut from the side but not ex-

tending deeper than one-third of the way to the center. The portions from both apex and side contained skin, buds, and the vascular cylinder. The center was the remainder, lying wholly within the vascular cylinder.

In a few cases (the Russet variety, table 3) large pieces of tissue were not used, but instead the bud was cut out with about 0.1 gram of tissue below it. Comparable pieces without buds were cut from the side and center of the tuber.

The data from these experiments (table 3, see also table 8) show that no auxin was obtained from the center of the tuber. When only the buds and tissue in their immediate vicinity were tested (Russet variety, table 3), the apical buds had more auxin than lateral buds. However, in one case the tubers were starting to grow, while in the other they were very near the end of their rest period. When the experiment was repeated with Bliss Triumph and White Rose tubers, which were known to be dormant, so little auxin was present that it was not possible to cut out enough buds so that a measurable amount of auxin could be extracted. For this reason, larger pieces of tissue were used. As auxin is absent from the center of the tuber, it must be in the vascular cylinder or in the comparatively thin cortex² surrounding it.

Examination of the potato tuber shows that the vascular cylinder is so shaped as to connect all the buds with one another (fig. 2). Therefore, if the auxin is mainly in the vascular bundles, auxin pro-

² According to Hayward (1938), the region between periderm and vascular cylinder is the cortex.

duced by one bud will readily be carried to others. Approximately the same situation will prevail if the auxin is in the cortex.

If the lateral buds are inhibited by auxin produced by the apical buds, it should be possible to cause similar inhibition by adding auxin artificially to the apical end of the tuber. To do this, tubers were selected

Fig. 2. Longitudinal section of Bliss Triumph potato tuber, showing relationship of buds and vascular cylinder.

which were nearly ready to come out of their rest period. One of the apical buds of each tuber (and a small area around it) was smeared with lanoline containing indoleacetic acid. Groups of ten tubers each were treated with lanoline containing indoleacetic acid in the following concentrations: 26, 3, 0.3, and 0.03 mg. per gram of lanoline. Controls were treated with pure lanoline. After six days the lanoline paste was scraped off.

When the tubers were given only the treatment described above, the auxin had no effect, although the

tubers were stored in boxes in the laboratory for several weeks. This was perhaps to be expected, however, for the apical buds inhibit the lateral buds even without the addition of indoleacetic acid.

In a parallel experiment which was done at the same time, the tubers were treated as above, but were also treated with ethylene chlorohydrin for three days immediately after the lanoline paste was applied. As shown below, this treatment removes the inhibiting effect of the apical buds on the lateral buds. If the indoleacetic acid which was added has any inhibiting effect, the lateral buds should show less growth on the tubers which were treated with indoleacetic acid than in those which were not.

After eleven days the buds were still too small for accurate measurement, but were classified as to size as follows: 0, no growth; 1, growth barely perceptible; 2, size of pin head; 3, rudimentary leaves showing; 4, bud swelling in diameter. In each tuber the following four buds were thus classified: the largest bud in the basal third of the tuber, the largest in the central third, the largest in the apical third, and the largest within 1 cm. of the apex. The addition of indoleacetic acid had no effect on the apical third of the tuber. As shown in table 4, however, it caused a significant reduction in bud growth in the middle third and basal third of the tuber.

It was mentioned above that the lanoline paste was scraped off the tubers after six days. It was subsequently applied unilaterally to *Avena* coleoptiles to estimate its auxin content. In the case of the paste containing 0.3 mg. indoleacetic acid per gram, the curvatures obtained were 14.5° for paste not applied to tubers, 13.1° for paste applied to tubers which were not treated with ethylene chlorohydrin, and 11.8° for paste applied to tubers which were also treated with chlorohydrin. For the paste containing 0.03 mg. per gram, the curvatures were, respectively, 5.8° , 4.4° , and 5.0° . Thus only a small part of the indoleacetic acid went into the tuber. As the supply did not become depleted, it may be assumed that indoleacetic acid was entering the tuber continuously

until the paste was removed (and for some time after, as not all the paste could be removed).

Interrelationship of buds in non-dormant tubers.—It would be desirable to know the auxin content of the buds during early stages of growth, but it has not been possible to determine this because of the small size of the buds. Such determinations were made, however, on Russet potatoes which were stored in the laboratory until the largest buds reached a length of about 3 mm. From five tubers all buds which were growing were removed. They had a total weight of 0.53 g. and were classified as six large, nine medium sized, and twenty-four small. The large ones were all from the apices of the tubers. Besides the buds, pieces of tissue taken from the apex and sides of the tubers were analyzed for auxin. The buds contained a large amount of auxin (table 5), the apex of the tuber (beneath the large buds) contained less auxin, and the sides the least auxin.

The experiment was also done with similar tubers which had been treated four weeks earlier with ethylene chlorohydrin. Here five tubers had fifteen large buds, twelve medium sized ones, and three small ones, totaling 2.07 grams in weight. The large buds were not confined to the apex of the tubers, but were formed on the sides as well. In this case the auxin content in the side portions of the tubers was the same as in the apices.

It has thus been shown that in the untreated tuber the buds contain more auxin than the tissue beneath the buds, and that the tissue beneath the large buds contains more than that beneath the small buds.

In order to show directly that large buds inhibit smaller buds, twenty-four dormant Russet tubers

were treated with ethylene chlorohydrin to make a number of buds start to grow on each tuber. A week later, the six largest buds on each tuber were numbered from 1 to 6 in order of decreasing size. The tubers were then placed for three weeks in moist sand in a dark room, after which they were washed free from sand and the stems were measured. The measurements (excluding a few injured or abnormal stems) are summarized in table 6. Most of the buds either did not grow (remaining shorter than 10 mm.) or grew rapidly (exceeding 100 mm. in length). All of the no. 1 buds grew, but, from no. 2 on, the percentage of buds which failed to grow became larger and larger.

After the stems were measured, all stems over 10 mm. long were removed from several of the tubers. These tubers were then replanted. Within a few days other buds, which had previously remained small, began to grow.

Thus, in each tuber the growth of the smaller buds was inhibited by larger buds. This occurred in a treated tuber where several buds had started to grow. In the untreated tuber, where only one or two apical buds start to grow, it is to be expected that growth of the remaining buds will be inhibited.

Effect of ethylene chlorohydrin on auxin in tubers.—The foregoing experiments indicate that auxin plays a rôle in the inhibition of lateral buds by apical buds. As this apical dominance disappears when dormant tubers are treated with ethylene chlorohydrin, it is possible that the action of ethylene chlorohydrin on the tuber is related in some way to auxin. For this reason, the effect of ethylene chlorohydrin on the

auxin content of potato tubers was made the subject of further experiments.

Tubers were treated with 1 gram ethylene chlorohydrin per kg. of tubers for periods of one to five days. Immediately after treatment they were analyzed for auxin. At the same time an analysis was made of similar but untreated tubers, and usually of a third group of tubers, which had been treated two or three days earlier in order to allow a storage period between treatment and analysis. The results of these analyses are shown in table 7 (see also table 5, part B).

This experiment shows that the auxin content was greatly decreased by the treatment, and that it rose again within two or three days after the end of the treatment. In all but two experiments the auxin content two or three days after treatment was considerably higher than in the untreated controls. Of these two exceptions, one was treated for one day and one for five days. These two treatments were shorter and

longer, respectively, than the optimum treatment of two or three days; for it has been shown (Michener, 1941) that one-day treatments do not accelerate germination as much as two- or three-day treatments, while treatments lasting four days may have an injurious effect, killing some of the tubers.

It is possible that ethylene chlorohydrin increases the rate at which auxin is destroyed in the tuber. Its effect on auxin destruction was determined by placing blocks of potato tissue, basal side down, on agar blocks containing a known amount of auxin. These blocks of potato tissue had previously been placed for two hours on wet filter paper to remove any auxin which might diffuse out. As shown in table 8, more auxin was destroyed by the treated tissue than by the untreated.

As the auxin reappears after the end of treatment, it is of interest to know where it comes from. As shown under "Discussion," there are several reasons for thinking it may be produced by the buds. Accord-

^a Analysis failed through accident.

ingly this possibility was investigated experimentally.

Tubers were treated with ethylene chlorohydrin after cutting out all the eyes, each with a small amount of tissue (about 4 cubic mm.) below it. A second group consisted of intact controls. To determine the effect of wounding, if any, a third group was prepared by cutting out pieces of tissue as in the first group, but cutting them out between the eyes, leaving the eyes intact. The tubers were then stored in a moist atmosphere for a few days to permit suberization of the cut surfaces. They were then treated as shown in table 9. In the first experiment the ethylene chlorohydrin treatment lasted two days, and in the second, one day. In the first experiment each auxin analysis was made on a composite sample of three tubers, and in the second only one tuber was used for each test.

In each of these experiments, the tubers with eyes removed had less auxin two days after treatment than did those which were left intact or those which were wounded between the eyes. The regeneration of auxin after treatment in the tubers without eyes was thus either totally lacking or lower than in the tubers with eyes.

With the possible exception of the last experiment, this work does not preclude the possibility that the reduced *Avena* curvatures obtained from treated tubers were due, not to destruction of auxin, but to ethylene chlorohydrin which might have been extracted along with the auxin and brought into the agar blocks in sufficient quantity to reduce the sensitivity of the *Avena* test. As the tubers were treated with 1 cc. of chlorohydrin per kg., they could have contained a maximum of 0.1 per cent chlorohydrin if all was absorbed and retained in the tuber. Accordingly an appropriate amount of indoleacetic acid was added to 90 cc. of a 0.1 per cent (by volume) ethylene chlorohydrin solution. A control was made with the same amount of indoleacetic acid but with water instead of chlorohydrin. These solutions were then shaken with 90 cc. of ether for half an hour on a shaking machine. This was repeated with a second portion of ether, which was then added to the first.

The ether was then evaporated and tested for auxin in the same manner as were the ether extracts from potatoes. The *Avena* curvatures obtained for the chlorohydrin solution and the control were, respectively, 16.7° and 19.5°. When part of the agar was diluted with an equal volume of pure agar the curvatures were 11.4° and 11.3°, respectively. A second experiment gave similar results. This eliminates any possibility that the ether extracts of treated potatoes could contain enough chlorohydrin to affect the auxin determinations.

Experiments were also done on the effect of ethylene chlorohydrin *in vitro*. Agar blocks were made containing 0.1 per cent chlorohydrin as well as auxin. These were tested for auxin, along with controls containing only auxin. One test gave curvatures of 20.7° with chlorohydrin and 19.7° without. With half as much auxin the curvatures were, respectively, 17.3° and 11.2°. In another experiment a solution containing auxin and 0.1 per cent chlorohydrin was allowed to stand for twenty hours. When tested it gave a curvature of 14.1° and the control gave 11.4°. Certainly, therefore, 0.1 per cent ethylene chlorohydrin does not decrease the *Avena* curvature or destroy indoleacetic acid *in vitro*. This also shows that the data presented in table 8 could not result from a direct effect of chlorohydrin on the *Avena* test.

DISCUSSION.—As described above, the terminal buds of an untreated potato tuber grow sooner than the lateral buds. This has been shown to be a correlation phenomenon rather than a fundamental difference between the buds themselves; for all buds grow at the same time if they are isolated from each other while completely dormant.

In this respect the potato tuber resembles growing stems such as those of pea seedling, where it is known (Thimann, 1939) that auxin produced by the terminal bud inhibits growth of the lateral buds. In the potato tuber, as in the pea stem, the buds are connected to one another by means of the vascular tissue. It has been shown that the auxin is present in the vascular tissue or in the cortex, where it is in close proximity to the buds.

The potato tuber also resembles the pea stem in that lateral bud growth may be inhibited by indoleacetic acid added to the apex. There is a difference in the method by which this can be carried out, however. In the pea stem, the natural source of auxin can be removed by cutting off the apical bud. Then the lateral buds grow unless indoleacetic acid (or another auxin) is supplied artificially to the apex. In the potato tuber cutting off the apex will, in itself, affect bud growth (Appleman, 1918). It is possible, however, to bring about destruction of a large part of the auxin by treating the tuber with ethylene chlorohydrin. After this treatment, indoleacetic acid applied to the apex has an inhibiting effect on the growth of the lateral buds.

This analogy between potato tuber and pea stem is of significance only if the auxin in the tuber is produced in part, at least, by the buds. This appears to be the case, for intact tubers regenerate auxin completely within two days after ethylene chlorohydrin treatment, while tubers from which the eyes have been removed regenerate little or no auxin in this length of time.

Evidence from other sources also supports this view. Rosa (1928) has shown that, while potato buds appear dormant, they actually enlarge to a considerable extent during the resting period, if the tubers are stored at a temperature favorable for growth. It is, therefore, reasonable to suppose that they produce auxin, especially in view of the work of Avery, Burkholder, and Creighton (1937) and of Bennett and Skoog (1938) showing that buds of deciduous trees begin to produce auxin in the spring before enough growth has occurred to produce visible swelling of the bud.

As the apical buds in the dormant tuber appear similar in size to the lateral buds, it is not clear how they can produce sufficient auxin to inhibit the lateral buds. However, Rosa (1928) states of a White Rose tuber which is "nearly full grown but still immature" that as this variety "shows strong apical dominance, the apical sprout is much further developed than any other on the tuber." If the apical bud is larger than the lateral buds, it probably produces more auxin than the lateral buds. In the potatoes used in these experiments, where the bud which grew was near but not always at the morphological apex, one or several of the apical buds might be larger than the lateral buds.

It may also be of significance that the terminal end of the tuber contains many more eyes than any other part. It may be seen from figure 1 that a large proportion of the eyes (perhaps 50 per cent) are in the apical region.

Also, the auxin in the potato tuber may be transported from apex towards base, as in many stems. If so, it is to be expected that auxin produced by apical buds will move towards lateral buds. It has not been possible to demonstrate polar transport of auxin in potato tissue. The rapid destruction of auxin by potato tissue, and perhaps also the small amount of

vascular tissue, make this phenomenon difficult to demonstrate in the potato tuber.

The relationship of apical and lateral buds has not been shown with certainty in the tuber which is just emerging from dormancy. It is much clearer after growth has proceeded to a point where the buds are several mm. long. At this stage large buds inhibit small ones, even when there is only a two or three-fold difference in size. In a normal, untreated tuber which has just germinated, there is a much greater difference in size than this between apical and lateral buds.

The auxin concentration in the growing buds at this stage is about ten times as high as in the apical tissue below the large buds, and about twenty times as high as in the tissue below the lateral buds, in which growth is inhibited. Thus the auxin concentration in the tuber decreases with distance from the apical buds. This is the condition which is necessary, according to Went (1939), to divert growth-promoting substances from the small, lateral buds to the large apical buds, thereby inhibiting growth of the lateral buds.

The experiments thus far discussed relate to inhibition of lateral buds by terminal buds in untreated tubers. The principles involved, however, appear to be related also to the effect of ethylene chlorohydrin on dormancy. It has been shown that ethylene chlorohydrin causes disappearance of much of the auxin in the tuber, and that the auxin reappears soon after treatment. This auxin which appears after treatment is produced in part, at least, by the buds.

Auxin produced after treatment will be transported from the buds into the surrounding tissue of the tuber. As this tissue has been depleted of auxin by the effect of the ethylene chlorohydrin, the new auxin coming from each bud will produce an auxin concentration gradient around the bud, with a high auxin concentration in the bud and a low concentration at some distance from the bud. According to the previously mentioned theory of Went (1939), this is the condition which would bring about growth of the buds, for it will bring about translocation towards the buds of materials necessary for growth. This concentration gradient around the buds either did not exist or was of less magnitude before treatment, for much more auxin was then present in the tuber.

It may then be asked why the tuber does not again accumulate auxin until bud growth is inhibited. Probably the initial stages of growth are accompanied by increased auxin production, and as the growth-rate increases the auxin production also increases, thus always maintaining the auxin concentration in the bud at a higher level than in the tuber. This view is supported by the fact that within two or three days after treatment the auxin concentration is often higher in treated tubers than in untreated controls.

It is of interest to note that Guthrie (1939) found that treatment of tubers or cut seed pieces with any of several different auxins prolonged dormancy, and even produced dormancy in tubers which would otherwise have grown immediately when placed in a

favorable environment. This dormancy could be broken by treatment with ethylene chlorohydrin. In view of the experiments described here, it may be concluded that ethylene chlorohydrin treatment causes destruction not only of naturally occurring auxin but of auxins artificially added to the tuber or brought into contact with cut surfaces of the tuber.

This hypothesis may also account for the fact that ethylene chlorohydrin accelerates bud growth even in tubers where the largest bud has reached a length of 1 mm. (Michener, 1941). Destruction of the auxin within the tuber will increase the steepness of the auxin concentration gradient between the bud, which produces auxin, and the tissue of the tuber, which has an abnormally low auxin content after treatment. According to Went's theory, this should increase the rate of translocation of growth-promoting substances towards the bud.

These experiments also agree with the previously stated hypothesis that apical dominance in germinating, untreated tubers is the result of auxin produced by the buds at the apex of the tuber. If this is correct, then disappearance of the auxin during treatment will cause disappearance of apical dominance and allow each bud to act independently. After treatment, of course, larger buds eventually produce enough auxin to inhibit the smaller ones; but, as shown in table 6, there are usually several buds which continue to grow in a treated tuber.

Guthrie (1939) also extracted auxin from potatoes after ethylene chlorohydrin treatment. As his extractions were made three to seven days after treatment, he failed to detect the sudden disappearance of auxin during treatment. In experiments in which he used the extraction technique of van Overbeek (1938), the auxin concentration in the treated tubers approximately equalled that in the controls by the time he made the extraction, which agrees with the experiments described here. The extraction technique of du Buy (1938) gave much lower auxin concentrations, and in this case the auxin content of the treated tubers was higher than that of the controls.

No experiments have been done by the author to determine the conditions which bring about the end of the rest period in untreated tubers. As Rosa (1928) has found that the buds continue to grow even during the rest period, it may be suggested that they finally produce auxin rapidly enough to cause movement of growth-promoting substances towards the bud.

It has been shown by Bushnell (1929) and Werner (1931) that apical dominance gradually disappears

if potatoes are in cold storage for several months. Experiments have not been done on this point either, but it is possible that buds fail to grow and produce auxin at a low temperature. If auxin destruction continues, this could lead eventually to depletion of the auxin in the tuber and consequent loss of apical dominance.

It is of interest to compare these experiments on ethylene chlorohydrin with those on ethylene (Michener, 1938). It was shown that ethylene causes auxin destruction at cut surfaces in pea seedlings, as does ethylene chlorohydrin in potato tubers.

SUMMARY

When the intact potato tuber begins to grow after its rest period, one or more apical buds grow, but the lateral buds usually fail to grow. If, however, lateral buds and apical buds are cut out and grown separately, both start to grow at the same time.

In non-dormant tubers, any large bud usually inhibits growth of smaller ones.

In non-dormant tubers, the auxin concentration is high in the large apical buds, lower in the tissue below them, and lowest in the tissue below the lateral buds.

In tubers in which apical dominance has been destroyed by treatment with ethylene chlorohydrin, application of indoleacetic acid to the apex of the tuber causes inhibition of the lateral buds. In other words, apical dominance can be produced artificially by applying indoleacetic acid to the apex of the tuber.

Therefore, it is probably auxin produced by the apical buds which correlates growth of apical and lateral buds when the tuber begins to grow after its rest period.

When the tuber is treated with ethylene chlorohydrin, much of its auxin disappears. Special experiments show an increase in auxin destruction at the time. The auxin reappears within two or three days after the end of treatment.

It is suggested that auxin inhibits bud growth in the dormant tuber, and that removal of the auxin by the action of ethylene chlorohydrin permits growth to proceed.

The disappearance of apical dominance which follows ethylene chlorohydrin treatment is also a result of the auxin destruction which takes place during the treatment.

INTERACTIONS OF AUXINS IN GROWTH AND INHIBITION¹

Folke Skoog, Charles L. Schneider, and Peter Malan

ALL KNOWN substances with auxin activity possess several common structural properties (*cf.* Koepfli, Thimann and Went, 1938). A few highly active compounds have been reported to have approximately equal activities in the pea test, and perhaps also in the *Avena* test when corrections are made for differences in transport rates (Thimann, 1935) and dissociation constants (D. Bonner, 1938), but many compounds remain which have a definitely lower order of activity even after such corrections are made. Thus in general the quantities of different substances required to produce a given response vary over a wide range.

Substances with structures indicative of auxin activity may also exhibit apparently qualitative differences in a given test method. Thus γ -phenylbutyric acid is almost inactive in the standard *Avena* test; it produces, at most, a slight increase in growth in section tests, and only small curvatures in the pea test. However, when plants are first treated with phenylbutyric acid and then some hours later with indoleacetic acid in the pea test (slit stem test), the response to low concentrations of indole-3-acetic acid will be very markedly increased (Went, 1939a) (see also Went 1939b and c). On the basis of this increase in activity, Went has proposed that phenylbutyric acid is a "hemi-auxin," *i.e.*, it possesses only those properties of an auxin which are effective in the first steps leading to growth. In this explanation two assumptions are made: (1) the activity of auxin is exerted in at least two separate reactions, and (2) different structural properties of the compounds are involved in the two reactions.

It follows from Went's interpretation of his pretreatment data either that indoleacetic acid (and also the auxin present in plant tissues) has the properties

required for the after-treatment to a higher degree than it has those required for the pretreatment, or that only a small proportion of the number of molecules taking part in the pretreatment reaction are needed for the after-treatment reaction. It is a necessary consequence that the application of indoleacetic acid in combination with phenylbutyric acid as well as in a separate pretreatment should be more effective than the application of the same concentration of indoleacetic acid alone. No data are available on this point. On the other hand, van Overbeek (1938), using the *Avena* test, has presented results, the quantitative significance of which is based on the assumption that the presence of phenylbutyric acid does not affect the magnitude of curvatures produced by indoleacetic acid or by auxin extracted from pea plants.

A further study of the effects of phenylbutyric acid on the growth promoting activity of indoleacetic acid is of interest both from theoretical and practical standpoints. Results obtained with various test methods are therefore presented below: These confirm Went's pretreatment results but show in addition that when phenylbutyric acid is supplied simultaneously with indoleacetic acid it markedly inhibits the activity of the latter. An explanation of this inhibition as well as of the stimulating effects of pretreatments with phenylbutyric acid is suggested in terms of quantitative rather than qualitative differences in activity of the two substances.

MATERIALS AND METHODS.—Combinations of serial dilutions of indole-3-acetic acid (IA) and γ -phenylbutyric acid (ϕ B) were tested by the following methods: (1) ordinary *Avena* tests (*cf.* Went and Thimann, 1937); (2) straight growth of decapitated coleoptiles supplied with the substances from agar blocks covering the cut surfaces (*cf.* Went,

¹ Received for publication March 31, 1942.

1935); (3) straight growth of coleoptile sections immersed in solutions with and without added sugar (cf. Schneider, 1938); (4) auxin transport tests with sections of *Tradescantia* internodes (cf. van der Weij, 1932); and (5) ether extraction of auxin (cf. Thimann and Skoog, 1940).

All experiments in which measurements of growth were made, including curvatures, were carried out with seedlings of *Avena sativa*, variety Victory, in a darkroom at 25°C. and 85 per cent relative humidity. Red light was used for illumination. Concentrations of auxin are quoted as milligrams per liter of medium (i.e., of distilled water or of 1.5 per cent agar). The volumes of the agar blocks were approximately 10 cubic millimeters each.

RESULTS.—*Avena* test curvatures.—Curvatures obtained with indoleacetic acid and phenylbutyric acid in the standard *Avena* test are shown in table 1. The most striking effect of phenylbutyric acid is that, instead of increasing the response to indoleacetic acid, it decreases or may completely prevent the curvatures normally obtainable from a given concentration of indoleacetic acid.

It may be seen further that phenylbutyric acid alone in the concentrations used in this experiment produces no significant curvatures. However, traces of activity (average ca. 1 degree) are frequently obtained with concentrations of 10 mg./l. or more. These curvatures are confined to the upper 2 or 3 mm. of the coleoptiles. Went (1939b) attributes such curvatures to the "hemiauxin" activity of phenylbutyric acid. If so, however, we should expect to have longer curved zones more nearly equal to those

produced by the auxin from the plant itself, because the transport of phenylbutyric acid is not restricted to short distances from the tip. The very short curved zones suggest rather that the phenylbutyric acid itself may have some auxin activity in very high concentrations (cf. Thimann and Schneider, 1939), or else that it exerts an acid effect (cf. J. Bonner, 1934).

The inhibiting effect of phenylbutyric acid on indoleacetic acid activity has been obtained consistently in some fifteen experiments. It cannot be ascribed to toxicity, because with low concentrations of indoleacetic acid clear cut inhibition is obtained with 2 and 10 mg./l. phenylbutyric acid, whereas with higher concentrations of indoleacetic acid even 50 mg./l. phenylbutyric acid exerts little if any inhibiting effect.

On the other hand phenylbutyric acid, in a range of concentrations from 0.1 to 50 mg./l., added to various concentrations of indoleacetic acid, has in no case led to an increase in curvature over that produced by the corresponding concentration of indoleacetic acid alone. Hence, in simultaneous treatments with the two substances in the *Avena* test phenylbutyric acid can neither be considered to carry out nor to facilitate exclusively any one reaction of an auxin. On the contrary the results show that the phenylbutyric acid blocks the action of the indoleacetic acid in accordance with the relative proportions in which the two substances are supplied.

Straight growth of decapitated coleoptiles.—Since curvatures are a measure of the relative increases in length of the two sides rather than of total elongation

TABLE 2. Percentage elongation of *Avena* coleoptiles to which combinations of *IA* and ϕB were supplied in agar. The measured zone, ca. 11. mm. long, extends downward from the cut surface.

of the coleoptile, the experiments above have been supplemented by others in which the agar blocks containing phenylbutyric acid, indoleacetic acid, or mixtures of the two were applied to the entire cut surfaces of the decapitated plants. Increments in length of the coleoptiles were measured with a horizontal microscope. The results of one such experiment are

Fig. 1-2. Per cent elongation of 3 mm. long sections of *Avena* coleoptiles in the section test with 2 per cent sucrose solution and various concentrations of indoleacetic and phenylbutyric acids. (The numbers inserted represent concentrations of indoleacetic acid in mg./l.)

presented in table 2. They show that the inhibitory action of phenylbutyric acid is also obtained in straight growth measurements. The only concentration of phenylbutyric acid indicating a possible stimulation was 0.5 mg./l. and even here the effect is so small as to be of doubtful significance. The measurements after fourteen hours are not quantitative, as the applied agar blocks give up most of their activity within the first five hours. They are included, nevertheless, to show that extensive growth is possible even after application of 50 mg./l. concentrations of phenylbutyric acid provided that sufficient indoleacetic acid is also supplied. They show also a long time inhibition of growth caused by the application of phenylbutyric acid alone or in conjunction with very low indoleacetic acid concentrations. This is not mainly a general effect of toxicity

but rather a specific inhibition of auxin action and probably also of auxin regeneration in the decapitated plants.

Growth of segments of coleoptiles in solution.—Segments of coleoptiles were immersed in solutions and their growth was measured. Three successive 3 mm. sections beginning at about 5 mm. below the tips of three-day-old coleoptiles were used. The experiments were done both with and without sucrose added to the solutions.

This method of immersing the tissues in solutions approaches the conditions of the "pea test"; correspondingly, it yields results more closely in agreement with those of the pea test in that a stimulating effect of phenylbutyric acid can be obtained. As shown in figures 1 and 2, increasing concentrations of phenylbutyric acid tend to increase the effectiveness of the low and intermediate concentrations of indoleacetic acid. Only in one case, however, that of 0.005 mg./l. indoleacetic acid, does the growth with added phenylbutyric acid actually surpass that of the controls with indoleacetic acid alone. This effect, while relatively small as observed in straight growth tests, would be pronounced in a curvature test which involves small differences in elongation of closely adjacent tissue layers. It may, therefore, compare

Fig. 3. Per cent elongation with indoleacetic acid (data from fig. 2. Explanation in text).

favorably with the pretreatment effect in the pea test. The concentrations used here are also very comparable with those found most effective for pretreatment, i.e., the concentration of phenylbutyric acid just below the toxic level, and the concentration of indoleacetic acid near to the threshold for increased growth. On the other hand it should be noted that these concentrations are the least suitable for determining independent qualitative effects of the two substances. The existence of a threshold value, which

is rather high for the pea test, indicates in itself that a considerable proportion of the applied indoleacetic acid is inactivated by the cut tissues, and this is corroborated by other evidence (cf. Thimann, 1934). It is possible, therefore, that the added phenylbutyric acid itself does not, except to a small extent, carry out any of the reactions leading to growth, but rather prevents destruction of the indoleacetic acid so that a greater fraction of the latter will be available for growth. This explanation is strongly supported by the results of the present experiments. In figure 3 is plotted the per cent increase in length of the sections against concentration of indoleacetic acid in treatments with this substance alone. It will be seen that the value for 0.005 mg./l. is abnormally low. In fact it appears as if this concentration had been entirely inactivated without contributing to growth. Furthermore even the highest response to this concentration of indoleacetic acid obtained by addition of phenylbutyric acid (value shown by large circle in the figure) is less than the value to be expected from the indoleacetic acid alone on the basis of the relationship between growth and concentration exhibited by the rest of the curve. It is concluded, therefore, that the increase caused by the addition of phenylbutyric acid is in large part due to its sparing action on the indoleacetic acid. This effect may become pronounced also for higher concentrations of indoleacetic acid in experiments of long duration.

A second most striking feature of the curves in figure 2 is the reduction in activity of indoleacetic acid by the low concentrations of phenylbutyric acid and the partial compensation for this reduction by the higher concentrations of phenylbutyric acid. This effect cannot be ascribed to a sparing action as above, since the same concentrations of indoleacetic acid alone produce even larger increases in growth than any of the mixtures. However, for this same reason it is also impossible to interpret the results in terms of a "hemiauxin" activity of phenylbutyric acid. This would require that the growth response to mixtures of intermediate (suboptimal) concentrations of indoleacetic acid and optimal concentrations of phenylbutyric acid should be as large as the response to the optimal concentration of indoleacetic acid alone. This result was never obtained. Here, as in the earlier experiments with the substances applied in agar blocks, there is rather a competition between the phenylbutyric and indoleacetic acids in the reaction system leading to growth. Granting this, the results of the present experiments can be interpreted in accordance with a simple general scheme for auxin action which will be presented below.

The rise of the curves in figure 2 with the higher concentrations of phenylbutyric acid cannot be explained in terms of simple competition between phenylbutyric and indoleacetic acids. These portions of the curves may, however, be included under this general scheme. For this purpose data are required regarding rates of formation and inactivation of the separate components of the auxin reaction system. The relative concentrations of these components will

be affected by the presence of phenylbutyric acid. Especially in long time experiments this may lead to changes in growth rates.

Effects of phenylbutyric acid on analyses for auxin activity.—The above experiments have made it clear that phenylbutyric acid mixed with indoleacetic acid in solutions supplied to test objects seriously reduces the activity of the indoleacetic acid in straight growth and curvature tests with *Avena*. Attempts have been made in experiments with both solutions and plant tissues containing phenylbutyric acid and indoleacetic acid to separate the active material by ether extractions, by diffusion, and by transport of the substances through plant tissues. The results indicate that the presence of phenylbutyric acid in plant tissues will prevent quantitative determinations of auxin by either extraction or diffusion methods.

1. Solutions extracted with ether.—In table 3 are shown results from an experiment in which comparisons were made of the activities of known concentrations of indoleacetic acid separately and in mixtures with phenylbutyric acid. Agar blocks for testing were prepared both directly from aqueous solutions and from ether extracts of these solutions. One cc. samples were extracted with three successive 0.5 cc. volumes of ether. The extracts were combined, evaporated to dryness and the residue was taken up in a one cc. volume of water from which agar blocks (1.5 per cent) were prepared. Some of these blocks were tested directly, others were first diluted to half the concentration by being placed in contact with equal sized agar blocks for one or two hours.

It may be seen that considerable indoleacetic acid activity was lost in the process of ether extraction. Thus the 0.03 mg./l. indoleacetic acid concentration gives 21.2° when the blocks are made directly and only 12.4° when they are made after ether extraction. (This loss is much less when larger volumes are used.)

It may be seen further that blocks made from ether extracts of mixtures of phenylbutyric acid and indoleacetic acid solutions give much lower curvatures than the extracts from the pure indoleacetic acid solution. On the whole the inhibiting effect of phenylbutyric acid was found to be relatively larger in the ether-extracted samples than in the original aqueous solutions. This is to be expected since the indoleacetic acid activity is less in the extracted samples (compare table 1). It is clear that the two substances cannot be quantitatively separated by ether extraction.

On the samples which were diluted to half concentration by diffusion into agar blocks separate tests were made on the original and added plain agar blocks. No difference in activity could be detected between the two, so that no separation of the substances was accomplished by diffusion in agar for one- or two-hour periods. (In tables 3 and 4 the mean values of both blocks are used.)

2. Plant tissues extracted with ether.—Sections of *Tradescantia* internodes were supplied with phenyl-

butyric acid, indoleacetic acid or mixtures of the two substances either by placing agar blocks on their apical cut surfaces or by immersing the entire sections in solutions for two hours. The sections were then rinsed in running distilled water for a few minutes, dried off on filter paper and placed in ether overnight for extraction at 2°C. The ether extracts were made into agar blocks as before and tested on *Avena*. In these experiments, carried out in 1938, difficulty was encountered in making appropriate dilutions within the range of concentration covered quantitatively by the *Avena* test, because the plant material was high and variable in auxin activity. In several cases the highest dilutions used for testing were above the range of linear proportionality. Nevertheless, the results show clearly that phenylbutyric acid inhibits the activity both of the auxin extracted from the plants themselves and of the indoleacetic acid added to the tissues. This was equally true, whether the phenylbutyric acid was first supplied to the tissues together with indoleacetic acid or the phenylbutyric acid was only added subsequently to the extracts. Thus, in one experiment extracts from tissues supplied with only water or indoleacetic acid solutions gave curvatures between 31 and 24 degrees in the lowest concentrations tested, whereas the same dilutions of extracts from plants supplied with phenylbutyric acid or mixtures of phenylbutyric acid and indoleacetic acid gave cur-

vatures between 5 and 20 degrees. It is clear from these results that no separation of phenylbutyric acid from indoleacetic acid or from the auxin in the plant can be obtained by ether extraction and subsequent diffusion through agar blocks. Thus the presence of phenylbutyric acid in tissues as well as in solution will prevent a quantitative estimation of auxin activity by methods now in use. In this respect phenylbutyric acid differs from the inhibitors which have been extracted from plant tissues (Goodwin, 1939; Larsen, 1936-1939; Stewart, 1939). The method proposed by Boysen-Jensen (1941) for separating auxin quantitatively from interfering substances by diffusion, therefore, may not be of general application.

3. *Auxin transport in tissues*.—In a series of experiments the transport of indoleacetic acid and phenylbutyric acid mixtures was studied. Sections of *Tradescantia* internodes 5 mm. long were placed with their morphologically basal surfaces on wet filter paper for about two hours to remove most of their free auxin content. The sections were then placed with their bases on plain agar blocks and other blocks containing indoleacetic acid and phenylbutyric acid in different combinations were placed on their apical surfaces. After two hours the sections were removed and the basal agar blocks were cut into smaller blocks for testing. Some of these blocks were, however, first diluted to one-half concentration by diffusion into

plain agar blocks as above, others were placed on equal sized blocks containing 0.06 mg./l. indoleacetic acid but no phenylbutyric acid. After two hours contact the blocks were separated and all were tested on *Avena* at the same time.

The results of one such experiment are presented in table 4. They show, first, that when mixtures of phenylbutyric acid and indoleacetic acid are supplied to the sections the activity obtained in the basal blocks is definitely less than when the same concentration of indoleacetic acid is supplied alone. Secondly, they show that the transport of indoleacetic acid is not prevented by the presence of phenylbutyric acid (curvatures of 17 and 7 degrees were obtained with the two concentrations of phenylbutyric acid used here); and thirdly, that the amounts of phenylbutyric acid transported through the sections are large enough, even in half concentrations, to inhibit markedly the activity of a 0.03 mg./l. concentration of indoleacetic acid in the *Avena* test. Thus the amounts of indoleacetic acid transported through the sections are also relatively large. The presence of phenylbutyric acid may have reduced the amount of indoleacetic acid transported, but the curvatures obtained indicate clearly that this effect if present must be very small. These results strikingly support the conclusion drawn from the results obtained with the "section tests" that the inhibiting effect exerted by phenylbutyric acid on the activity of indoleacetic acid is not mainly due to interference with the transport of indoleacetic acid through the plant tissues.

A mechanism for the interaction of auxins in growth and inhibition.—Results of many types of experiments, including measurements of respiration, growth, and the oxygen sensitive protoplasmic streaming, have shown that under suitable conditions indoleacetic acid will accelerate and under other conditions it will inhibit the rates of all these processes (Thimann and Sweeney, 1937; Sweeney and Thimann, 1938; Commoner and Thimann, 1941). These experiments as well as those of Schneider (1938) have shown an intimate relationship between auxin and carbohydrates and indicate that indoleacetic acid acts in fact as a respiratory coenzyme. Warburg and co-workers (Warburg, 1937) have demonstrated the chemical nature and general properties of some such coenzymes and have shown that they are functional only in combination with proteins, *i.e.*, they form reactive parts of large molecular aggregates. Evidence for the existence of auxin-protein complexes in plant tissues has also been obtained (Skoog and Thimann, 1940; Thimann and Skoog, 1940). Even though there is no proof that the fraction of auxin which is active exists in such a complex this seems likely.

Auxin activity then will depend on two separate properties: (1) structural configuration required for the molecule to occupy definite positions in the large molecular aggregate and (2) a specific chemically reactive group. That these two sets of properties are actually required and are characteristic of all known

substances with auxin activity has been clearly brought out in the studies of comparative auxin activities of benzene, indole and naphthalene derivatives (Kögl and Kostermans, 1935; Koepfli, Thimann and Went, 1938). Briefly the minimal require-

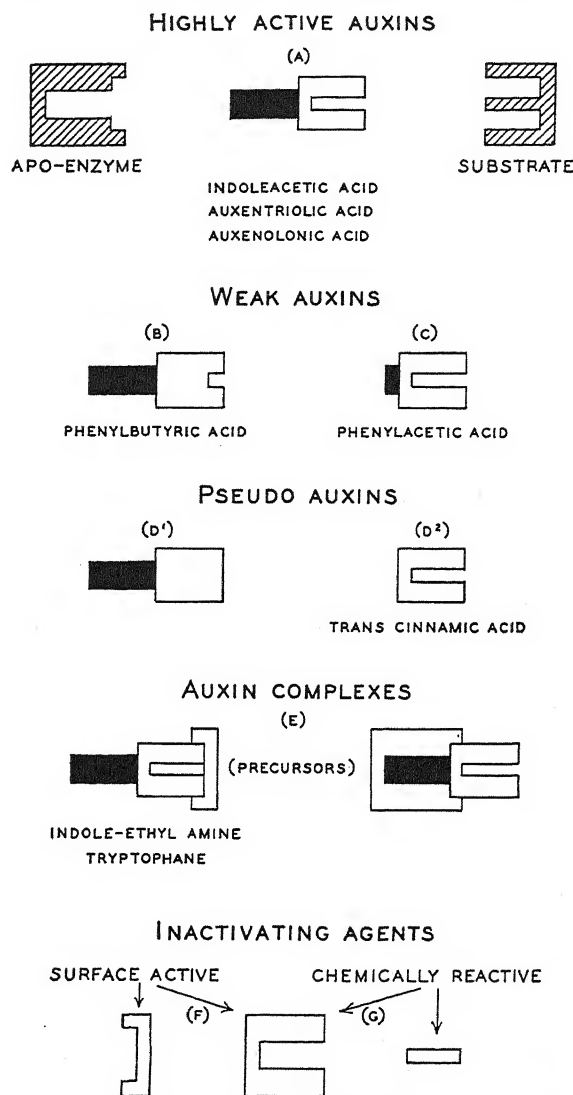

Fig. 4. Diagram representing relative activities and types of action of auxins. (Markedly inhibitory substances are on the left side, and highly chemically reactive substances on the right.)

ments include a ring system with a side chain containing at least 1 carbon atom in addition to a terminal carboxyl or potential carboxyl group, a double bond in the ring joining the carbon atom linked to the side chain, and a particular spacial relationship between the ring and the carboxyl group. These properties may be represented diagrammatically as in figure 4. A very active auxin such as indoleacetic acid or auxin A is given by (A). Here the required structural configuration is represented by a bar pro-

jecting to the left, and the chemical reactivity by the depth of the slit to the right. This distinction is of course arbitrary in that modifications in structure within the limits of the required configuration may quantitatively affect the reactivity of the molecule. Nevertheless, it serves to differentiate between two main criteria of activity. There are accordingly two types of weak auxins. One type (B) has the required structural configuration to compete successfully for positions in the reacting system but is able to react chemically only slowly. Hence, if present alone in high concentration, such a substance may cause appreciable growth, but in the presence of more active auxins it will act mainly as an inhibitor. An exception to this is where the concentration of the more active auxin is so low that the sum of the activities of the two substances, together with the sparing action of the former on the latter, will be greater than the competitive inhibitory effect. A second type (C) has high reactivity, but due to structural deficiencies it is unable to meet successfully the spacial requirements. Substances of this group, too, may be slightly active in high concentrations, but they will not act efficiently as inhibitors. Rather if they are able to react independently with available substrate groups, they may act as inactivating agents. According to this scheme "pseudo auxin" in which the double bond shifts from the ring to the side chain, thus completely removing auxin activity (Kögl, Königberger and Erxleben, 1936), will have the configuration shown in (D_1) if the double bond forms a part of the reactive group, which seems likely; or (D_2) if the double bond is merely a part of the configurational requirements. The inhibitor extracted from plant tissues and which is convertible to active auxin (Stewart, 1939; Stewart, Bergren and Redemann, 1939) would be represented by the structure (E). To this group would also belong such substances as tryptophane and indolethyl amine which likewise act as inhibitors but can be converted into active auxins (Skoog, 1937).

On the other hand, one substance, phenylacetic acid, has been reported active as an auxin in inducing parthenocarpic fruit development but completely inactive as an inhibitor of bud development (Gustafson, 1941). It can be readily seen that this behavior, which finds no explanation in earlier concepts of auxin action, would be expected as typical of substances in group (C) of the present scheme.

In addition to the above types it is of course possible to have two kinds of more or less specific inhibitors and inactivating agents as indicated in (F) and (G), which are able to combine or to react with the active substance and thus affect growth without themselves having the structure of auxins.

It is realized that a simple scheme of this nature can be only an approximate representation of the actual situation. Nevertheless, it has the advantage of making it possible to bring together the most diverse effects both quantitative and qualitative into one simple concept. This concept, furthermore, has had a wide application to physiological processes. It may

be unique in its application to auxins only in this respect, that there is a large number of known active substances and that there are several types of effects which may be estimated by different methods. Furthermore, these methods are all relative, so that negative as well as positive values can be recorded in terms of distinct effects on growth.

The above scheme will account for the inhibition of growth by a relatively high concentration of a single active auxin on the assumption that in the presence of excess auxin some molecules will be attached to the enzyme system and others to the active groups of the substrate thus effectively blocking each other from reacting.

Competitive auxin action and the mechanism of bud inhibition.—The present scheme makes possible an extension of the "direct mechanism" of auxin action in bud inhibition presented by Thimann and Skoog (1934), Thimann (1937), and Skoog (1939). The term *direct* has been generally used to designate an effect exerted by the auxin in the inhibited bud as opposed to effects which may be produced on the bud indirectly as a result of influences of auxin on the utilization or translocation in the stem of nutrients and more or less specific growth factors toward or away from regions of active growth.

Some principal objections raised to the concept of *direct* auxin action in inhibition can now be met. One of these has been based on the fact that the application of very low auxin concentrations to decapitated plants or isolated buds will stimulate rather than inhibit bud development (Thimann, 1937; Went, 1939b; Skoog, 1939). This result can be explained as follows: In the period immediately after decapitation of the stem or removal of the buds, the free auxin content of the latter is known to be very low. Small additional amounts of auxin may, therefore, be absorbed by the available enzyme-substrate system without its saturation value for optimal growth being exceeded. Addition of low concentrations will hence lead to acceleration rather than inhibition of bud growth.

A second objection has been that on the basis of mass action one auxin cannot be considered to affect the formation or activity of another chemically different substance (as, for example, indoleacetic acid affects auxin A). This difficulty is eliminated when it is recognized that the relationship between the substances depends not on their being chemically identical but is determined by their ability to occupy the same position in a large molecular aggregate.

Another observation, hitherto unaccounted for, can be explained. This is the necessity for a continuous supply of auxin to a bud to effectively inhibit its growth. A total concentration much higher than that actually required for complete inhibition of growth when the supply is maintained at a constant rate is completely ineffective when supplied in such a manner that, for short intervals between applications, the concentration is allowed to fall to a very low level. It is clear that in these intervals growth of the bud will proceed at optimal rates and as the bud en-

larges, increasingly higher dosages will be required for inhibition of its growth.

It has been reported that the concentration of auxin in a bud cannot be a determining factor in the inhibition of bud development, as inhibited buds may contain either higher or lower total extractable amounts of auxin than growing buds (van Overbeek, 1938; Ferman, 1938). It must be considered, however, that conditions leading to inhibition are determined not by the concentration of *total extractable* auxin but by the relative concentrations of the *free* auxin, enzyme proteins and substrates, *i.e.*, by the equilibrium between auxin and other components of its reaction system. Now it becomes evident that organs or tissues may have very different auxin concentration requirements for growth, as for example roots and shoots, or adjacent tissue layers in the stem, and further that these requirements will vary for each organ in its successive stages of development. It follows, moreover, that in correlative inhibition, as in the inhibition of one developing bud by another, the auxin of the inhibited bud may be actually decreasing in quantity at the same time that it is becoming increasingly effective in inhibitory action, as the supply of substrate is being utilized by the more rapidly growing bud. As soon as the slightest difference in growth rates arises between two buds the auxin system will begin to act as an automatic device facilitating and gradually making effective a complete shift of growth from one bud to the other. This interpretation concedes the importance of factors other than auxin in correlative inhibition. Yet it emphasizes the special rôle of auxin as an immediate or direct regulatory agent. The controversial question whether auxin acts directly in the bud or indirectly in the stem becomes irrelevant. It is clear that inhibition can be and under experimental conditions has been accomplished by a sufficiently high concentration of hormone in the bud itself. If, however, at the same time, as in intact plants, auxin present in the stem causes acceleration of growth and utilization of substrate, then the concentration of auxin required in the lateral bud to cause inhibition of its growth will be greatly reduced.

Finally it has been suggested that the variety in types of growth responses obtained with different auxins in a single plant or with a single auxin in different plants precludes the possibility of a single general auxin reaction (Hitchcock and Zimmerman, 1938; Went, 1939a). From a consideration of auxin-apoenzyme-substrate equilibria, identical final growth responses can be expected only from identical cells treated alike with the same substance, no matter how simple may be the chemical reaction carried out by the auxin molecule itself. (Compare variability in behavior of plant dehydrogenases.) Therefore, the type of response will depend not on the auxin reaction but on the structural configuration of the auxin molecule and on the types of protein and substrate with which it is combined.

CONCLUSION.—Concepts which have been proposed to explain the action of auxins and the rela-

tive activities of different auxins are inadequate to account for effects obtained with mixtures of phenylbutyric and indoleacetic acids on the growth of *Avena* coleoptiles. A consideration of these effects and the evidence from recent literature on the action of auxins suggests rather a general scheme for auxin action essentially similar to that employed for the action of coenzymes. Briefly it contains the following points:

(1) The properties of auxin essential for its activity are (a) a structural configuration which will allow it to occupy specific positions in a larger molecular aggregate, and (b) a specific chemically reactive group.

(2) The relative activities of different auxins are determined by each of these requirements, though the two may be in part interrelated.

(3) Auxins with adequate structural configuration but with low chemical reactivity will compete with more active substances for available positions in the enzyme-substrate system and will thus block the action of the latter (examples: phenylbutyric acid, indolethyl amine, auxin-precursor from radish).

(4) Auxins with high reactivity but with less adequate structure will have low activity and will not function effectively as inhibitors (example: phenylacetic acid).

(5) High concentrations of a highly active auxin will also lead to growth inhibition by the effective blocking of one molecule by another from simultaneous contact with both enzyme and substrate.

The above scheme for the action of auxin is incomplete in details and may need modifications. Nevertheless, it covers the salient features of available experimental data. It permits the integration of the large variety of effects resulting from auxin activity in plants including interpretations of several hitherto unexplainable observations. It does so without ascribing qualitative differences to separate active substances and without introducing any peculiarities other than structural configuration to the auxins as a group. The main reason for its presentation, however, is that it offers a new approach for experiments on the function of auxin especially in relation to associated factors in the growth of plants.

SUMMARY

The effects on growth of indole-3-acetic and γ -phenylbutyric acids supplied separately and in mixtures have been studied by various standard methods in the *Avena* coleoptile.

The results show that phenylbutyric acid might possess slight auxin activity, but when it is administered in combination with indoleacetic acid, its main effect is to inhibit the activity of the latter. The extent of this inhibition is a function of the relative concentrations of the two substances and is, therefore, ascribed to competitive action between them.

The presence of phenylbutyric acid in solutions or plant tissues prevents quantitative estimations of their auxin activity (plant auxin or indoleacetic acid). Phenylbutyric acid cannot be effectively elimi-

nated for analytical purposes by ether extraction, diffusion in agar blocks or transport through plant tissues.

Phenylbutyric acid does not possess the properties implied in the definition of a "hemiauxin." The increase in response to indoleacetic acid elicited in the presence of phenylbutyric acid under certain conditions is attributed to an acid effect or a slight auxin activity of high concentrations of phenylbutyric acid and its "sparing action" especially on low concentrations of indoleacetic acid.

The results conform to the view that auxin acts as a coenzyme.

On this basis a scheme is presented for the action of auxins in stimulation and inhibition of growth.

This scheme affixes an important determinative rôle also to interactions between auxin and its

enzyme-substrate complex. It thus provides for the contribution of formative effects from the cell milieu and nutrients, and it avoids ascribing separate kinds of activity to different auxins to account for discrepancies in the types of response they may produce. Hence it emphasizes the immediate regulatory or correlative action of auxin in the growth process, and it accounts for the ability of auxin to accelerate or inhibit growth as a quantitative manifestation of a single function rather than as results of separate qualitative effects.

DEVELOPMENT OF THE OVULE AND THE FORMATION OF THE SEED IN *PLANTAGO LANCEOLATA*¹

Geo. Olds Cooper

PLANTAGO LANCEOLATA L. (rib grass, ripple grass, English plantain) has been investigated by McCullagh (1934) and Tjebbes (1928) for the chromosome number, and by Souèges (1926) for polyembryony. The stages in microsporogenesis follow the usual history found in many of the angiosperms (Cooper 1935, 1938). Little detailed study of the development of the ovule prior to fertilization has been made. The development of the embryo of *Plantago* was studied by Souèges in 1923. The recent investigations of Cooper (1941) on *Phryma leptostachya* and Farley and Hutchinson (1941) on *Medicago* have shown the functional relationship of the vascular strand to the development of the endosperm and the embryo.

MATERIALS AND METHODS.—Floral spikes of *Plantago lanceolata* L. were gathered on the campus of the University of Wisconsin. They were fixed either in Carnoy's solution or in Karpenchenko's modification of Navashin's solution, embedded in paraffin, sectioned at 12–14 μ , and stained in Delafield's haematoxylin.

DEVELOPMENT OF THE OVULE.—The floral spike is at first capitate, later becoming cylindrical. Each flower bears a single pistil of two united carpels. Each carpel produces a single ovule, and the two ovules are borne on the axile placenta. The archesporial cell differentiates early in the hypodermal layer at the apex of the ovule. This cell is easily identified, since its cytoplasm is denser and the nucleus is larger than in the surrounding cells of the ovule (fig. 1). When the archesporial cell has become fully differentiated the single integument appears as a meristematic outgrowth from the chalazal cells immediately below the archesporial cell and grows upward and about the apex of the nucellus (fig. 2, 3). As the integument is forming, there is a more rapid growth of the ovule on the side away from the main axis and the ovule bends downward and around toward the base of the ovary. This bending continues as growth progresses, so that the ovule is anatropous at maturity. The nucellus consists of a single layer of cells around the archesporial cell except at the chalazal end. The integument becomes massive and a long micropyle leads to the nucellus (fig. 10, N) which is now deeply embedded within the ovule. The cells of the nucellus toward the micropylar end as the megagametophyte approaches maturity have elongated and flattened and, shortly after fertilization, disappear.

In the early development of the ovule the main vascular strand of the ovary extends into the axis part way to the base of the ovules (fig. 2). It differentiates further as the ovules increase in size and the

axis elongates. A branch from the main vascular strand penetrates the funiculus to the chalazal end of each ovule and is separated from the mature megagametophyte by several layers of parenchyma cells which function as conducting cells (fig. 10). These cells are undifferentiated and are uniform in their cytoplasmic content. However as the megagametophyte matures the adjacent conducting cells elongate slightly, and the cytoplasm becomes highly vacuolate (fig. 11). The conducting tissue nearer the apex of the vascular strand is made up of cells in active mitosis and elongation. They remain finely vacuolate until the ovule is almost mature. These conducting cells function in osmotic conduction from the vascular strand to the developing megagametophyte. The vascular strand in the later stages in the development of the ovule can be distinguished at the tip of the funiculus between the micropylar and chalazal haustoria. The funiculus appears narrower due to the active development of the micropylar and chalazal haustoria which have digested the parenchyma of the funiculus between the ovule and the placenta (fig. 19, 21). The remaining parenchyma cells of the funiculus have lost most of their cytoplasmic content prior to the formation of the abscission layer.

MEGASPOROGENESIS AND THE DEVELOPMENT OF THE MEGAGAMETOPHYTE.—The archesporial cell functions as the megaspore mother cell and enlarges and elongates while the integument is growing. The cytoplasm of this cell becomes finely vacuolate, and the nucleus enlarges during the early stages of meiosis. Six pairs of chromosomes are present at diakinesis (fig. 4). Likewise, at the heterotypic metaphase (fig. 5) and at the heterotypic anaphase six pairs of chromosomes are present (fig. 6). A linear tetrad results from the two meiotic divisions (fig. 7). The megaspore toward the chalazal end becomes the functional megaspore. The three megaspores at the micropylar end disintegrate before the megagametophyte is formed. The nucleus of the persisting megaspore divides mitotically so that a two-nucleate cell results. The two nuclei of this cell migrate apart, one going toward the micropylar end and the other toward the chalazal end (fig. 8). These nuclei divide again (fig. 9), two remaining at the chalazal end of the developing megagametophyte and two at the micropylar end. Cell walls appear following a third division of these nuclei and a typical seven-celled megagametophyte is formed consisting of three antipodals, two synergids, the egg cell and the large primary endosperm cell (fig. 12). The two antipodals at the chalazal end are elongated and lie side by side; the third is cubical and is located below the other two and adjacent to the primary endosperm mother cell. The synergids, obovate in shape with a deep staining granular cytoplasm, surround in part the egg cell. The egg is large and pear-shaped with a reticulate cytoplasm that is finally vacuolate about

First division of endosperm nucleus. $\times 450$.—Fig. 16. Presence of pollen tubes after fer-

the nucleus and coarsely vacuolate at its pointed end. The two polar nuclei fuse shortly after the formation of the megagametophyte. Starch grains are present in the egg and the primary endosperm mother cell only. An abundance of starch is present in the endothelial layer and adjoining cells of the integument at the micropylar end and to a lesser degree at the chalazal end about the megagametophyte.

FURTHER DEVELOPMENT OF THE OVULE.—The cells of the nucellus toward the micropylar end, which have elongated and separated from one another during the development of the megagametophyte, disappear shortly after fertilization (fig. 14). Both ovules of a given pistil mature in flowers at the base of the floral spike, whereas in late maturing flowers one ovule may become a seed while the other one, not being fertilized, may become aborted. Pollination in any particular flower occurs before the anthers of that flower mature. A high percentage of sterility is present in the pollen grains in the anthers. Several pollen tubes may enter a megagametophyte prior to fertilization and persist for a time after the formation of the zygote (fig. 16). The collapsed tube nucleus and the two shrunken male gamete cells can be seen within an inactive pollen tube (fig. 16, A).

FERTILIZATION AND EARLY DEVELOPMENT OF THE ENDOSPERM.—Double fertilization occurs; the nucleus of one male gamete unites with the nucleus of the egg, the other with the primary endosperm nucleus (fig. 13). The nuclei of the egg cell and the primary endosperm cell now show a marked increase in size (fig. 14). Following the first division of the endosperm nucleus (fig. 15, 16), a cell-plate is formed. The dividing wall lies diagonally across the primary endosperm cell (fig. 17). The nucleus of the chalazal cell divides again, remains binucleate, and the nuclei increase in size. The micropylar cell undergoes two divisions to form four cells that partly surround the zygote (fig. 18). The two outer cells are larger and conical (fig. 18, A); the two inner cells are more or less cubical. The two inner cells undergo further divisions and in time produce the endosperm proper, consisting of many thin-walled cells, except for the peripheral layer which has thick walls and dense cytoplasmic content. This layer retains its characteristic appearance throughout the further growth of the endosperm. The endosperm is at first spherical in shape, later becoming kidney-shaped. The antipodals meanwhile have disintegrated and the synergids which persisted for a time disappear.

DEVELOPMENT AND BEHAVIOR OF THE HAUSTORIA.—Haustoria are developed from specialized cells of the endosperm and aid in the conduction of food from the cells of the integument and nucellus to the developing embryo and endosperm proper. The lower cell in the two-celled endosperm stage functions as the chalazal haustorium. As it digests its way through the parenchyma of the funiculus to the placenta it elongates and becomes club-shaped at the growing

tip, with greatly enlarged nuclei. Continued growth of the chalazal haustorium in time separates the basal portion of the ovule from the placenta, except for the few cells about the vascular strand in the funiculus (fig. 19, 21). The two outer cells derived from the divisions of the micropylar cell of the two-celled endosperm are uninucleate in structure, rarely becoming binucleate and function as the micropylar haustoria. These micropylar haustoria are spreading in their growth and at their extremities produce pseudopodium-like outgrowths (fig. 21). The pseudopodial outgrowths apparently secrete substances which digest the parenchyma of the funiculus and the placenta so that in time the funiculus appears much reduced in size between the chalazal and micropylar haustoria. The cytoplasm of the haustoria is highly vacuolate and is denser at the tips of the pseudopodium-like outgrowths that are in contact with the cells of the integument. The presence of an abundance of starch in the cells of the integument adjacent to these haustoria indicates the presence of stored foods which may possibly stimulate their growth upon being digested. The middle lamellae of the cells of the integument are absorbed first, later the adjacent walls and finally the cellular content (fig. 22). Similar behavior of the mature haustoria was observed by Balicka-Iwanowska (1899) and Souèges (1926).

Branches from the micropylar and chalazal haustoria were observed penetrating and digesting the outer portion of the ovule adjacent to the developing endosperm. These branches differ slightly from the main haustoria in that they contain no nuclei and are highly vacuolate with concentrated amounts of cytoplasm at their tips (fig. 19, A). The growth of these haustorial branches throughout the chalazal end and the outer region of the integument likewise differ from the main haustoria in that, whenever a branch tip penetrates the integument, there seems to be pressure exerted, and the adjacent cells of the integument become flattened and elongated (fig. 20).

DEVELOPMENT OF THE SEED.—The division of the zygote to form the apical cell and the basal cell in the early development of the embryo is delayed until the endosperm with its haustoria is well differentiated (fig. 19). The apical cell of the embryo in a series of divisions forms the embryo proper, and the basal cell divides to form the suspensor. The course of development of the embryo is in accord with the description of Souèges (1923) for the species. As the hypocotyl and the cotyledons grow, the epicotyl is recognized as an opaque region at the apex of the embryo between the cotyledons. The developing embryo lies in a plane parallel to the longitudinal axis of the ovule (fig. 23). The embryo within the surrounding endosperm does not become very large and absorbs only a small amount of the endosperm. The endosperm however absorbs most of the surrounding integument as it increases in size, so that only a few cell layers

tilization. $\times 450$.—Fig. 17. Second division of endosperm nuclei. Cell at chalazal end functions as haustorium. $\times 450$.—Fig. 18. Chalazal haustorium with two nuclei; conical cells (A) become micropylar haustoria; cubical cells become the endosperm proper. $\times 450$.

Fig. 19-30.—Fig. 19. Two-celled embryo surrounded by endosperm; developing chalazal and micropylar haustoria absorbing the parenchyma of funiculus toward the placenta. Branches from haustoria digesting integument. Vascular strand and conducting tissue in the funiculus. $\times 350$.—Fig. 20. Detail of region (A) of figure 19 showing the digestion

of the integument remain (fig. 24). At maturity the endosperm with its characteristic surface layer of cells occupies the major portion of the seed and completely surrounds the embryo. The remaining cells of the integument become much elongated in forming the seed coat, lose most of their cytoplasmic content and are papery at the time of seed dispersal (fig. 25, 26). The mature seed contains the embryo, embedded in an abundant endosperm, and a papery seed coat. Remains of the micropylar and chalazal haustoria are present in the locule between the seed and the axis of the ovule.

SUMMARY

Each carpel of the two-loculed pistil contains an ovule which is anatropous at maturity.

A single archesporial cell in the hypodermal layer of the ovule functions as the megaspore mother cell. A single massive integument is formed.

Six pairs of chromosomes are present at meiosis.

Four megaspores are formed in a linear row and the chalazal megaspore develops into an eight-nucleate, seven-celled megagametophyte; the other megaspores disintegrate. The cells of the nucellus begin to disintegrate at this stage.

A vascular strand is differentiated early in the funiculus to the chalazal end of the ovule and functions in conduction from the main vascular strand of the ovary to the conducting cells at the chalazal end of the megagametophyte.

Abundant starch is present in the integument about the megagametophyte and, to a lesser degree, in the primary endosperm cell and the egg.

Double fertilization occurs. The endosperm divides to form two cells; the chalazal cell becomes binucleate and functions as an haustorium. The micropylar cell divides to form four cells, two of which by a series of divisions form the endosperm proper; the remaining two function as the micropylar haustoria. The growth of these haustoria in time separates the ovule from the placenta, except for the vascular strand of the funiculus.

The developing endosperm is delineated by a definite row of cells that persist even in the mature seed.

The zygote does not divide until the endosperm has become many-celled.

The mature seed with its papery seed coat contains the embryo embedded within the endosperm.

OBSERVATIONS ON THE GENUS *BLASTOCLADIELLA*¹

J. N. Couch and Alma J. Whiffen

THE GENUS *Blastocladiella*, discovered by Matthews in 1937, is a saprophytic aquatic phycomycete which in its thallus structure is intermediate between the simplest fungi, the Chytridiales, and some of the more complex forms such as *Blastocladia* or *Allomyces*. At present the genus is composed of the original species *B. simplex* Matthews and *B. variabilis* Harder & Sörgel. *B. simplex* produces zoosporangia and non-sexual resting sporangia and thus has a simple life cycle without any alternation of sporophytic and gametophytic asexual and sexual generations. In soil collections from South Carolina and Texas, we have isolated three new species of this rare genus. The two from South Carolina have life histories similar to *B. simplex*, but the one from Texas has a life cycle which differs from that of any other species in the genus.

ISOLATION AND DEVELOPMENT OF THE NEW SPECIES.—The two species from South Carolina were found on the same piece of boiled grass leaf, occurring there when the grass leaf was first examined, in the form of a few zoosporangia and smooth and warted-walled resting sporangia which might be either stalked or sessile. It was at first suspected that we had found the resting sporangia of *Clavochytridium stomophilum*. The two species were isolated in unifungal culture in the following way. Part of a leaf with zoosporangia and resting bodies was cut out and put in a Petri dish with a fresh piece of a boiled leaf of *Paspalum* grass and water. Twenty-four hours later on part of this piece of leaf there was what appeared to be a pure growth of the new chytrid. This part of the leaf was cut out and put on 3 per cent plain agar, and then, under a binocular microscope, eleven single zoosporangia were dissected out from the leaf tissue, each dragged to a fresh part of the agar, then cut out with a small block of agar and transferred to the surface of a new piece of leaf in a sterile dish. In some of these isolations and in the cultures descended from them, only resting sporangia with rough walls have appeared, and in others only the smooth-walled resting sporangia. It was thus established that the rough- and smooth-walled resting sporangia belonged to different species. The species with rough-walled resting sporangia is given the name *Blastocladiella aspersperma*, the smooth-walled one is *B. laevisperma*.

In these two species of *Blastocladiella* the development is much the same and appears to be quite similar to that of *B. simplex* as described by Matthews (1937).

The following observations have been written up from notes made on *B. laevisperma*. The zoospore encysts and sends out a delicate germ tube which branches and enlarges to become the rhizoidal system (fig. 16, 17, 18). The spore itself enlarges great-

ly to form the stalked or sessile zoosporangium or resting sporangium. In the development of the zoosporangia the protoplasm in the early stages shows the pale, whitish gleam characteristic of the chytrids, with minute vacuoles and numerous fat bodies of variable size. The fat bodies, however, are never so large as in such chytrid forms as *Rhizophidium*. As development proceeds the protoplasm becomes more conspicuously vacuolated and densely granular. Just before the zoosporangium reaches its mature size the numerous fat bodies break up into small particles and become evenly dispersed through the protoplasm (fig. 19, 20). Soon after the basal wall is formed, the tiny globules become arranged in a reticulate fashion (fig. 21). About this time one or more emergence papillae are formed and simultaneously the tiny globules collect into small groups, a group in the center of each spore origin (fig. 22). A few minutes later the outlines of the zoospores appear as rounded, clear areas each with several small globules (fig. 23). In some sporangia just after the spores are completely formed the spore mass near the center may start cyclic motion which increases in vigor until most of the spores have been discharged. In other sporangia there is no autonomous movement of the spores until after they emerge.

When the spores are ready to emerge, the hyaline cap of the papilla gelatinizes, and part of the spores push out into this hyaline substance to form a spherical mass. The spores are retained in this ball for only a few seconds, for the gelatinous membrane quickly breaks and the spores swim away. The remaining spores emerge one or several at a time depending upon the size of the emergence pore. As seen under a dark field the spores swim smoothly in a hardly perceptible spiral path rotating clockwise on their axes, the cilium showing alternating single and double images. All quiet spores showed a conspicuous tail piece on the cilium under the dark field.

In the development of the resting sporangia in *B. aspersperma*, *B. laevisperma*, and *B. simplex* we have been unable to detect any fusions of zoospores. Such fusions may occur, for we have not followed the development of a single unfused zoospore into a resting body. Thalli developed from single zoospore strains produce both zoosporangia and resting bodies, which indicates the absence of sexual strains and the absence of an alternation of sexual and asexual generations. In the early stages of development the thalli of resting sporangia cannot be differentiated from those of zoosporangia. After they have reached mature size, however, the protoplasts of the resting sporangia shrink from the original enclosing membrane and secrete a new, thick, double-layered wall which becomes the wall of the resting sporangium. The resting sporangia are capable of germination only after a rest period of several weeks, and, though we have tried a number of experiments to shorten this period, we have so far been unable to

¹ Received for publication April 27, 1942.

This work was supported by a grant from the Penrose Fund of the American Philosophical Society.

do so. We have found, furthermore, that prolonged drying of the resting sporangia of *B. aspersperma* and *B. laevisperma* on pieces of leaves in Petri dishes kills them; whereas similar treatment or even drying for as long as a year has no effect on the vitality of the resting sporangia of *B. simplex* or the new species from Texas. The process of germination is essentially alike in all species of *Blastocladiella* which we have studied.

In *Blastocladiella variabilis*, Harder and Sörgel (1938) have described a fungus with a much more complex life cycle than is found in the "simplex" group. In that species there is a distinct alternation of generations, the sporophyte generation consisting of two kinds of plants: a zoosporangial and a resting sporangial plant. The former gives rise to zoospores which germinate to produce either another zoosporangial thallus or a resting sporangial thallus, but when the latter germinates it gives rise to two kinds of zoospores, one of which grows into the plus or female gametangial thallus; the other growing into the minus or male gametangial thallus. The female gametangium is colorless, the male faintly reddish, and they form uniciliated gametes which fuse in pairs to form a zygote that grows either into a zoosporangium or a resting sporangium. The life cycle of this organism and of *Sphaerocladia* (see below) represent the most complex life cycles yet described in the lower fungi and, perhaps, in all fungi save the rusts, for here are found a distinct alternation of sexual and asexual generations and, furthermore, the sexual plants are heterothallic.

A third type of life cycle is illustrated by *Blastocladiella cystogena*, so called because of its cyst-forming habit. This heretofore undescribed fungus was isolated in April, 1940, from soil from Texas, but was not critically examined until after our studies on the two species from South Carolina were well under way. Indeed, the form from Texas was passed over by us as *B. simplex*, and it was only when we wished to compare that species with the ones from South Carolina that Miss Whiffen discovered that, when the resting sporangia of the form from Texas germinated, the zoospores encysted in an irregular mass, the contents of each cyst giving rise to four uniciliated zoospores. Further studies showed that these uniciliated zoospores fused in pairs to form a biciliated zygote which develops into a resting body. It is very likely that the plant body here is diploid and that only the gametes are haploid. Any definite conclusion, however, as to when reduction division occurs must await the outcome of detailed cytological studies now being made by Miss Hendricks in our laboratory.

In the development of this fungus we shall concern ourselves here only with the germination of the resting sporangia and the formation and fusion of the gametes.

The mature resting sporangia vary from colorless and thin-walled to thick-walled brown bodies. Some are capable of germinating immediately after their formation, while others seem to require a rest period.

Resting sporangia dried on a piece of leaf in a Petri dish were still capable of germination after a year. One may hasten the germination of resting sporangia by drying them for forty-eight hours or longer and then adding water. Pouring off the water from old cultures and adding fresh water will bring on germinations. Abundant germinations have been obtained at room temperature (18° to 24°). The first sign of germination is the appearance of several narrow fissures in the brownish outer wall through which the gray protoplasm in the sporangium can be seen. (fig. 1, 2, 49, 50). Due to the continued swelling of the contents of the sporangium, the fissures widen and open into each other thus making an irregular tear in the outer wall. Through this opening one or two papillae grow out, after which the swarmers are delimited in the sporangium (fig. 1-3). In some sporangia the swarmers or zoospores show active movement before emerging, while in others they are inactive before reaching the outside. The zoospores emerge as in other species of *Blastocladiella* (fig. 4, 5). The end of the papilla gelatinizes, and some of the zoospores push outward, forming a spherical mass within a gelatinous sac. This gelatinous envelop quickly dissolves, and the remaining spores left in the sporangium emerge. The spores, though furnished with cilia, do not as a rule swim away as they emerge. They may swim for a short distance settling in the same field, but usually they stick together in one or more irregular heaps or twisted rope-like masses, their cilia waving for a few minutes before encystment (fig. 6). The cysts are spherical and usually of uniform size and contain hyaline protoplasm with a number of small yellowish globules (fig. 6, 7). The period of encystment lasts from thirty minutes to an hour.

About fifteen minutes after encystment a papilla is formed on each cyst, and shortly thereafter the protoplasm in each one is divided into four parts, each of which becomes a gamete (fig. 7, 58). It is likely that during gametogenesis a meiotic nuclear division occurs. Almost immediately after cleavage is complete the gametes begin to emerge. The first one to emerge pushes slowly through the papilla thus creating an opening, and the other three follow slowly one at a time. Sometimes one gamete may take as long as a minute to flow through the narrow pore. The four gametes from a cyst usually remain clustered for a few seconds or minutes at the mouth of the cyst, their cilia jerking feebly (fig. 7, 58). Each gamete is uniciliated and contains one nucleus with a conspicuous and characteristic body forming a cap over the part of the nucleus away from the cilium. Since there is considerable difference of opinion as to the nature of this body, we are calling it simply the nuclear cap. To the side of the nucleus and nuclear cap is a clump of several shiny, yellowish fat globules. The anterior end of the gamete is hyaline except for a few granules (fig. 59, a). It has been stated above that each cyst gives rise to four gametes, and this is the rule with rare exceptions, where, perhaps due to incomplete cleavage, a cyst may give rise to

two biciliate structures. There is a remarkable simultaneousness about the emergence of the gametes from the same clump of cysts, so that, only a few minutes after the first have come out, the whole mass is seething with gametes.

Observations on fusing gametes have been made under a water immersion lens with a cover slip over the material, the presence of which did not seem at all to interfere with their activity. The cover glass, however, should be supported to prevent its weight from crushing the cysts. This support may be fur-

with it. Sometimes it may be slow to fuse with any one of the tetrad, the whole mass of five gametes gliding over one another for one or two minutes before fusion is effected. After cytoplasmic fusion has occurred it usually takes several seconds for the zygote to become organized for swimming. If the gametes have fused laterally with both cilia pointing in the same direction, this reorganization is relatively rapid. The two nuclear caps come in contact and flow together like two drops of oil; the two cilia come to lie parallel and very close together, perhaps

nished by keeping ample water under the cover slip and by mounting several extra resting sporangia with the ones about to discharge. When the gametes emerge, they may remain clustered at the cyst for a few seconds or minutes, after which they may break away and creep over the other gametes and cysts until fusion with a compatible partner occurs. Fusion usually occurs so quickly and with so little movement that one is likely to overlook the event (fig. 59). One sees two gametes side by side, and suddenly in their place appears a biciliated zygote. Fusions occur most frequently between gametes lying side by side with both cilia pointed in the same direction, but fusion may start from any part of the membrane. Gametes from the same cyst have not been observed to fuse with each other, but a gamete from a different cyst may swim or creep up to the cluster (fig. 59) and fuse immediately with the first gamete it touches, or it may move on to another and fuse

actually in contact; the nuclei fuse, though this cannot be clearly observed in living material; and the numerous yellowish fat globules come together in one compact clump, though they do not fuse. However, if the gametes have begun to fuse with their cilia not in the same direction it may take a minute or two and violent struggling before the cilia and the internal parts become properly oriented (fig. 61, a-d). In the process of fusion the two gametes show about an equal amount of activity, though sometimes one may be more active than the other or the two may alternate in brief periods of activity. Not infrequently two violently struggling gametes apparently in the act of fusing may be approached by a third gamete which immediately quietly fuses with one of the partners, the zygote swimming away and the unfused gamete creeping off to try its fortune elsewhere. Sometimes while the gametes are gliding over each other one may send out a pseudopodium which,

playing against the membrane of the opposite gamete, makes a connection, and then after a considerable struggle fusion is completed (fig. 62, a-k). Two gametes may become connected in this way and yet not fuse, for sometimes one of the gametes may jerk so violently as to break the connection and swim away (fig. 60). Again a third gamete may appear and quickly fuse with one of the two after which the zygote becomes free.

After fusion is complete the zygote suddenly gives several violent lunges to free itself from gametes, cysts or other entanglements and then swims away. The swimming zygotes were observed under the dark field, and it was found that the two cilia were so closely applied to each other as to appear as one, and, moreover, that they functioned as one in propelling the zygote (fig. 59e, 62k). The cilia do not fuse, however, for when a zygote stops swimming for a few seconds, the two cilia may separate from each other along their entire lengths. This behavior seemed rather unusual to us, for in abnormally biciliate spores of the chytrids, as in *Rhizophlyctis rosea*, the two cilia have never been observed to act as one. We have also found that the two cilia on the zygote of *Allomyces javanicus* functioned as one, just as in the zygote of *B. cystogena*. In the chytrids there is sometimes a fusion of motile cells, as in *Pringsheimiella dioica*, but it is possible that only when a true sexual fusion occurs do the two cilia become associated and act as one.

Fusion stages have also been observed in stained material. Excellent preparations can be made by fixing material in water on the slide for thirty seconds in fumes of 1 per cent osmic acid, and then staining with very dilute gentian violet. The violet should be so dilute that when the drop is held over white paper it is only faintly colored. If such a preparation is examined immediately under a water immersion lens, one can find various stages of nuclear fusions (fig. 63a-c). By the time the two cilia have come so close as to appear as one, the two nuclei have fused. The two cilia are as a rule in this position on the living zygote before it swims away, and one may, therefore, conclude that at this stage in living material the nuclei have fused.

TAXONOMY OF THE GENUS.—With the discovery of the three new species of *Blastocladiella* and particularly *B. cystogena*, the need for an extension of the limits of the genus is quite obvious. At the same time the question arises as to the taxonomic position of the two recently described genera, *Clavochytridium* and *Sphaerocladia*.

Clavochytridium (Cox, 1939) is certainly much closer to *Blastocladiella* than was thought when the former was first described. Indeed except for their larger size and usually swollen base, the zoosporangial thalli of *Cl. stomophilum* can hardly be distinguished from stalked zoosporangia of *B. aspersperma* and *B. laevisperma*. The zoospores also are alike in structure but differ slightly in behavior during discharge, a distinction which in view of the similarities seems hardly of generic value. We are, therefore, transferring *Cl. stomophilum* to the genus *Blastocladiella*.

The genus *Sphaerocladia* which has a life cycle very much like that of *B. variabilis* is separated from *Blastocladiella* by the spherical shape and the presence of a "seitenkörper" in the zoospore of the former. Stüben (1939) grew his plants on flies and on various types of nutrient agar. When grown on agar under a cover glass, stalked forms were produced. Under the culture conditions used by Stüben, we doubt if the absence of a stalk is of sufficient significance to justify separation from *Blastocladiella*. On agar and on leaves *B. simplex* may or may not have a stalk. On agar *B. cystogena*, *B. stomophilum* and *B. laevisperma* are never stalked, and the rhizoids may arise from any point on the surface of the zoosporangium or resting sporangium. On leaves *B. stomophilum* is usually stalked, *B. cystogena* is usually without a stalk or with a very inconspicuous short one and *B. laevisperma* and *B. aspersperma* are as frequently sessile as stalked. When grown on hemp seed in water, the stalked forms predominate in *B. simplex*, *B. cystogena*, *B. aspersperma*, and *B. laevisperma*.

Another basis for the separation of *Sphaerocladia* from *Blastocladiella* is in the presence of a side body (seitenkörper) in the zoospore of the former. In the living zoospores of *B. simplex*, *B. laevisperma* and *B. aspersperma* we are unable to find with certainty any structures which would be interpreted as Stüben's side body. However, when the zoospores of these species are killed with the fumes of osmic acid and weakly stained with an aqueous solution of gentian violet and studied immediately without drying, a very conspicuous curved body is visible. In *B. laevisperma* and *B. aspersperma* this body extends from near the rhizoplast over the nucleus and nuclear cap usually almost to the opposite end of the spore, varying somewhat in size in different spores (fig. 65, 66). The nuclear cap is deep purple or almost black, while the side body is much less deeply stained and appears to be hollow or vesicular in structure (fig. 63-66, s.b.) In *B. simplex* the side

body is shorter and thicker than in the other species but has the same vesicular appearance. A particularly good view of the side body and indeed of the entire contents is shown in the spore in figure 64 in which the parts were considerably swollen and the plasma membrane had begun to disintegrate. The side body was much enlarged, purplish and clearly

Blastocladiella, as well as the two genera *Clavochytridium* and *Sphaerocladia*.

BLASTOCLADIELLA Matthews 1937, em. Harder & Sörgel 1938, 1939

Rhopalomyces Harder & Sörgel 1938

Clavochytridium Couch & Cox, in Cox 1939

Sphaerocladia Stüben 1939

Thallus microscopic, unicellular, consisting of a single extramatrical, tubular, pyriform or globose part anchored to the substratum by a branched rhizoidal system; extramatrical part giving rise to a stalked or sessile, thin-walled zoosporangium, resting sporangium, or gametangium. Thin-walled zoosporangia usually present, globose to cylindrical with one to several discharge papillae. Zoospores posteriorly uniciliate, with a nuclear cap over the anterior part of the nucleus and with several laterally placed fat or lipid globules. Thick-walled resting sporangia usually present, enclosed in the old thallus membrane; wall of resting sporangium composed of two distinct layers: the outer brownish, thick, usually sculptured layer, and the inner, hyaline, thin, smooth layer; outer layer coarsely or minutely areolate, warted or smooth or smooth except for one or several ridges. Resting sporangia germinating by the cracking of the exospore wall into two or several irregular pieces after which the hyaline inner part sends out one or more papillae through which zoospores emerge to form zoosporangia and/or resting sporangia, or to grow into thallose gametangia, or to encyst, the cysts acting as gametangia and germinating to release four gametes which fuse in pairs to form a zygote. Cell walls not giving a cellulose reaction with chloriodide of zinc.

On plant or animal substrata in fresh water habitats or on soil subject to flooding.

KEY TO THE SPECIES OF *BLASTOCLADIELLA*.

A. Short life cycle, only one generation

1. Both zoosporangia and resting sporangia present

- a. Thalli more than 500 μ tall; resting sporangia distinctly areolate *B. simplex*
- b. Thalli less than 500 μ tall

- i. Resting sporangia warted *B. aspersperma*
- ii. Resting sporangia smooth *B. laevisperma*

2. Only zoosporangia present

- a. Thalli frequently up to 300 μ tall and usually stalked on leaves *B. stomophilum*

B. Long life cycle, two equal generations, asexual and sexual

- 1. Sporangia and gametangia usually stalked; male gametangium orange *B. variabilis*

- 2. Sporangia and gametangia usually sessile; both gametangia colorless *B. Stübenii*

C. Short life cycle, only resting sporangia and cysts which act as gametangia formed *B. cystogena*

BLASTOCLADIELLA aspersperma n. sp.²—Thalli clavati vel globosi, basi cum rhizoideis; thalli duabus formis, similibus magnitudine et figura, altera zoosporangia, altera sporangia perdurantia parienti;

vesicular. Adhering to the side body were the darkened fat bodies. There seemed to be an intimate association between the rhizoplast and the side body. Indeed it seemed that the cilium was attached both to the side body and the rhizoplast. With the discovery of side bodies in the zoospores of the type species of *Blastocladiella*, and three other species in addition, the final distinction between *Blastocladiella* and *Sphaerocladia* falls down and *Sphaerocladia variabilis* must be transferred to *Blastocladiella*. We suggest the name *Blastocladiella Stübenii*.

The following generic description and key to the species are drawn up to include all known species of

zoosporangiiis 25–100 μ diam. vel usque ad 88 \times 155 μ ; stipite nullo vel stipite usque ad 30 \times 150 μ . Zoosporis uniflagellatis, 3.6–4.6 \times 6–7 μ . Sporangiiis perdurantibus capsam non plene explentibus, globosis vel subcylindricis, fere 14–80 μ diam. (globosis); pariete flavo-brunneo, distincte verrucoso.

Thalli consisting of extramatrical stalked or sessile zoosporangia and resting sporangia anchored to the substratum by rhizoids; single or caespitose. Zoosporangial thalli spherical, ovoid, pyriform or nearly cylindrical; sporangia spherical, pyriform, ovoid, sub-cylindrical or irregular; 25–100 μ thick when spherical, up to 88 \times 155 μ when ovoid or pyriform; stalk when present varying from a small basal part to a long tube 30 \times 150 μ , usually thickest just below the sporangium, frequently with one to several rings just below sporangium. Sporangia with one to several (up to 11) emergence papillae. Zoospores usually becoming active in sporangium before emergence. The first spores emerging in a spherical vesicle formed from the gelatinized tip. After the vesicle bursts the spores remaining in the sporangium emerge slowly and swim away immediately upon reaching the outside. Zoospores 3.6–4.6 \times 6–7 μ . Resting sporangial thalli similar in shape, size and early development to the zoosporangial thalli; resting sporangia not completely filling the case in which they are formed; spherical, ovoid, pyriform or sub-cylindrical; outer wall yellow brown and distinctly warted; 14–80 μ thick on grass when spherical, somewhat larger on hemp seed and spherical to oval in shape. Germinating after several weeks' rest to form zoospores as in zoosporangia.

On pieces of boiled *Paspalum* grass leaves from soil collected in roadside ditch by Philip Couch on way to Middleton Gardens, South Carolina, June 15, 1941. This species is named *B. aspersperma* because of the rough walled resting spore.

BLASTOCLADIELLA laevisperma n. sp.—Thalli clavati vel globosi, basi cum rhizoideis; thalli duabus formis, similibus magnitudine et figura, altera zoosporangia, altera sporangia perdurantia parienti; zoosporangiiis 25–117 μ diam.; stipite nullo vel stipite usque ad 26 \times 105 μ . Zoosporis uniflagellatis, 3.8–4.6 \times 6–6.5 μ . Sporangiiis perdurantibus globosis vel subcylindricis, raro duobus sporangiiis perdurantibus in eodem thallo formati, fere vel plene capsam explentibus; pariete rubro-brunneo, laevi praeter lineas elevatas paucas.

Zoosporangial and resting sporangial thalli much as in *B. aspersperma* except resting sporangia usually fill the case and have a smooth wall except for a few ridges. Zoosporangia usually sessile on leaves and stalked on hemp seed; 25–117 μ when spherical; stalk up to 26 \times 105 μ . Zoospores 3.8–4.6 \times 6–6.5 μ when active, 5–5.4 μ when rounded up. Resting sporangial case as a rule stalked on hemp seed but usually sessile on leaves; rarely two resting sporangia may be formed on the same stalk; spherical, ovoid, pyriform or sub-cylindrical, sometimes constricted in the middle, at times lobed; 25–140 μ thick when spherical, up to 63 \times 95 μ

when ovoid; stalk 30 \times 155 μ , broadest at the top; resting sporangia usually completely filling the case and conforming to its shape, up to 126 μ thick when spherical; wall 1.5–2.8 μ thick, reddish brown or pale dull yellow, smooth except for one or several conspicuous ridges. Germinating after a few weeks' rest to form zoospores which are similar to those from zoosporangia.

In the same soil collection with *B. aspersperma*. The name *B. laevisperma* is given because of the smooth-walled resting sporangium.

The two species may be distinguished by differences in the resting sporangia. In *B. laevisperma* the resting sporangia are reddish brown, smooth walled and usually fill the case, while in *B. aspersperma* the resting sporangia are yellowish brown, with a coarsely warted wall and only partly fill the case.

BLASTOCLADIELLA cystogena n. sp.—Thalli nulli zoosporangia parientes; thalli sporangia perdurantia stipitati vel sessiles, basi cum rhizoideis, parientes. Sporangiiis perdurantibus globosis vel subglobosis, 16–342 diam. (globosis) vel 37–142 \times 39–564 μ ; pariete duplici, parte exteriori laevi vel minute areolata, prope hyalina vel aureo-brunnea; ut in genere germinantibus. Zoosporis uniflagellatis, extemplo in sporas immotas (cystae) massa irregulari transformati. Sporis immotis (gametangia) 8.2–10.2 μ diam., globosis. Omni spora immota quatuor cellulas sexuales uniflagellatas parienti, quae binae conjunctae zygosporas biflagellatas formant.

Zoosporangial thalli lacking in life cycle. Resting sporangial thalli when on leaves usually extramatrical, spherical or pyriform and sessile or with a very small and inconspicuous stalk, frequently intramatrical on leaves and then subspherical ovoid or lobed; on hemp seed usually tubular, the case that encloses the resting sporangium globose to subcylindrical. Rhizoids well developed, attached basally if sporangium is extramatrical, or attached to several places on the sides if intramatrical. Resting sporangia when spherical 16–342 μ thick, when subspherical 37–142 \times 35–209 μ ; stalk when present very variable in size, 30–116 \times 39–564 μ ; usually filling the case in which it is formed; wall two-layered, very faintly areolate, 1.5–6.1 μ thick, nearly hyaline to dull yellow or orange brown. Germination as in the genus. Zoospores uniciliate when discharged, encysting almost immediately near the sporangial mouth in an irregular mass. Encysted spores (gametangia) 8.2–10.2 μ thick, spherical. After one to two hours each cyst gives rise to four unciliated gametes which emerge through a minute pore to fuse in pairs near the empty cysts; gametes 4.1 \times 4.9 μ . Zygotes biciliated, 6 \times 8 μ , swimming for an hour or more before germinating to form resting sporangia.

On pieces of boiled *Paspalum* grass leaves from soil collected by Philip Couch March 20, 1940, at Laredo, Texas. This species is named *B. cystogena* because of the occurrence of an encystment stage when the zoospores emerge from the resting sporangia.

The above species is readily distinguished from all other species of *Blastocladiella* by the absence of a thin wall zoosporangial stage and by the life cycle with cysts and isoplanogametes.

DISCUSSION.—Miss Matthews (1937) in her original description of *Blastocladiella simplex* emphasized its close relationship to the Blastocladales, a viewpoint the correctness of which has been corroborated by the researches of Harder and Sörgel (1938) and our own. In the genus *Blastocladia*, the type of life cycle present is largely unknown except in the one species *B. Pringsheimii*, which has recently been studied in detail by Miss Blackwell (1940). This has the short life cycle as in *Blastocladiella simplex*. In *Allomyces* the life cycle types are much better known than in *Blastocladia*.

Emerson (1938, 1939, 1941) has shown that there are three distinct types of life cycles in *Allomyces*: (1) *Euallomyces* has the long cycle with sporophytic and gametophytic generations; (2) *Brachyallomyces* has the short cycle with only the zoosporangial and resting spore stage; and (3) *Cystogenes* has a short cycle with a cyst stage. There is a striking similarity between two of the types of life cycles found in *Allomyces* and in *Blastocladiella*, a fact recognized by Emerson (1941). *B. variabilis* and *B. Stübenii* have life cycles of the *Euallomyces* type, as found in *A. arbusculus*; *B. simplex*, *B. aspersperma*, and *B. laevisperma* have life cycles of the *Brachyallomyces* types, as seen in *A. anomalus*. In addition to these two types we are adding a third which in certain respects is markedly similar to the *Cystogenes* type in *Allomyces*. In *A. cystogena* the same thallus produces thin-walled zoosporangia and pitted-walled resting sporangia. According to Emerson the latter germinate to produce biciliated zoospores which emerge to encyst at the mouth of the sporangium. The cysts later give rise to zoospores, usually four from each cyst, which swim for some time and then grow into plants like the parent. According to Emerson (1938, 1939, 1941) there is no gametic fusion in the cystogenes group of *Allomyces* though he has suggested that sexual fusions may take place during the germination of the resistant sporangia. In a paper which has just appeared McCranie (1942) describes observations which are at complete variance with those of Emerson. McCranie, using Emerson's Burma 1B isolate, reports that the spores from the resistant sporangia were without cilia encysting in a group near the sporangial opening. Immediately or after a rest period of variable duration the cysts give rise to secondary swarmers which become semi-amoeboid and copulate in pairs to form a biciliate zygote. In view of these strikingly different results, it is obvious that more work must be done on the cystogenes group of *Allomyces*. In *Blastocladiella cystogena* the thallus produces only resting sporangia and unciliated spores, which after encystment give rise to isogamous planogametes. These fuse in pairs to form a biciliate zygote. If we accept Emerson's description of the life cycle of *Allomyces cystogenus*, it is only in the production of

cysts that *Blastocladiella cystogena* resembles that species. If McCranie is right, however, then the parallel between the two is most striking indeed; for then it is highly probable that the vegetative thalli in both fungi are diploid.

It has been thought by all students of this group of fungi that *Blastocladiella* was a connecting link between the Blastocladales and the Chytridiales. If we believe in the ascending evolution of these forms, there can be little doubt that *Blastocladiella* represents the most primitive type of the Blastocladales. However, in spite of the close similarity of thallus shape in *Blastocladiella* to some of the Chytrids, there is no chytrid genus which appears to be very closely related to *Blastocladiella*. Of all the Chytrids known, perhaps *Cylindrochytrium* (Karling, 1941) resembles *Blastocladiella* most closely in thallus structure. This relationship, however, is not very close, for in *Cylindrochytrium* the zoospores and resting bodies are typically chytridiaceous, while this is not true in *Blastocladiella*. The zoospores of *Rhizophlyctis rosea* contain several small refractive globules as do those in *Blastocladiella*, but in cell wall and resting sporangial structure the two differ markedly. In the Blastocladales the resting sporangia may or may not completely fill the case; however, in all species the wall of the resting sporangium is readily separable from the outer case, as indicated by the freeing of the resting sporangium from the case in *Allomyces*, while in the Chytridiales the resting sporangium usually completely fills this wall. The resting bodies of the chytrids, with few exceptions, germinate by the formation of a zoosporangium outside of the old resting body, while in *Blastocladiella* and its relatives the resting body is transformed directly into a zoosporangium. In *Rozella*, *Pringsheimiella* and *Olpidium* the resting body germinates much as in *Blastocladiella*.

Although there seems to be no single chytrid genus that is closely related to *Blastocladiella*, there are certain basic morphological features shared commonly by the Chytridiales and the Blastocladales. All chytrids and members of the Blastocladales have the whiplash type of cilium (Couch, 1941) and are posteriorly ciliated even when there are two cilia. One structural feature which was supposed to be peculiar to the Blastocladales is the nuclear cap in the spore. Karling (1937) and Hillegas (1940), however, have described nuclear caps in several genera of the Chytridiales, and it is very likely that such structures are of common occurrence in this order. Thus it seems that the motile cells are basically alike in the two orders except for the usual presence of only one fat globule in the zoospore of the chytrids, while in the Blastocladales there are several fat bodies. It may be that the side body of Stüben is peculiar to the Blastocladales. Before this can be determined, however, a comparative study of the internal structure of the zoospores in the Chytridiales must be made.

The nuclear cap is one of the most striking characteristics of the *Blastocladia* type of spore and will

probably be found in all true chytrids. This cap is undoubtedly of phylogenetic importance, and it is of significance that Debaisieux (1920) has described such a structure in *Coelomycidium simulii*. This latter organism is, in the opinion of Debaisieux, closely related to the Chytrids and is put by him in this order. We are of the opinion, however, that *Coelomycidium*, while perhaps not a true Chytrid, is more closely related to the Chytridiales than to the Plasmodiophorales or the Protozoa.

SUMMARY

In soil collections from South Carolina and Texas three new species of *Blastocladiella* have been isolated. Two of these, *B. aspersperma* and *B. laevisperma*, have short life cycles without any alternation of generations and without sexuality like *B. simplex*. The other, *B. cystogena*, has a new type of life

cycle. It lacks the typical zoosporangial stage, but forms thick-walled, brownish-orange resting bodies, which after maturity may be brought to germination. When this happens, a large mass of unciliated zoospores emerge, which, instead of swimming, encyst in an irregular heap. After about an hour, the contents of each cyst divide into four unciliated gametes which emerge and fuse in pairs, no fusion occurring between gametes from the same cyst. The zygotes swim for some time, the two cilia acting as one, and then come to rest and germinate to form resting bodies. It is likely that reduction occurs when the gametes are formed, and, if so, the thallus of this species is diploid. A new description of the genus is given to include *B. cystogena*, *Clavochytridium stomophilum* and *Sphaerocladia variabilis*.

DRAWING GUIDE FOR ZINC ETCHINGS

Letters, lines, and dots in relation to reduction for the printed page. Top—Reduction to 1/4. Middle—Reduction to 1/2. Bottom—Original size.

Reprinted by permission of the authors from: RYKER, A. J., and REICHA S. RYKER. 1936. *Introduction to research on plant diseases*. 117 p. Published by the Authors, Department of Plant Pathology, University of Wisconsin, Madison, Wis.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

NOTES ON THE ORIGIN OF ADVENTITIOUS ROOTS IN THE NATIVE ONTARIO CONIFERS ¹

M. W. Bannan

MUCH STUDY has been given of late to the propagation of conifers by cuttings (Deuber, 1940; Deuber and Farrar, 1940; Farrar and Grace, 1942; Griffith, 1940; Thimann and Delisle, 1942, and others). Considerable work has been done on determining the most satisfactory media for setting out, the best time of year for collection, the most suitable kinds of cuttings to use, and the concentration and types of hormones which are most effective in promoting root development. The anatomy of root formation, on the other hand, has received only slight attention, and in the present paper it is proposed to deal with this aspect of the problem. It should be emphasized, however, that the descriptions which follow apply only to layered material collected from the field, and not to specimens which have been experimentally treated in the laboratory.

TAXUS.—The prostrate *Taxus canadensis* Marsh is common in southern Ontario, less so in northern parts of the province. It sometimes grows in the open, but more often is found on the forest floor in the more deeply shaded woods. The decumbent branches are frequently covered by débris for much

of their length, and these buried parts are generally rooted.

As a rule the roots are not scattered singly along the branch but are grouped near the bases of lateral branches. Sometimes the lateral branches have rotted away (fig. 1); in other cases they are living (fig. 2) and may be almost as large as the principal branch. The roots in each group are sometimes even-aged, transverse sections showing all to have arisen in the same year; whereas in other instances various members in the group were initiated in different years. Some roots are short-lived; others attain considerable size with several rings of secondary xylem.

The relationships between adventitious roots and the xylem tissues of the branch are illustrated from transverse sections in figures 9–11. The first-formed cells of the tissue associated with root development are parenchyma cells which, as shown in the figures, are arranged in radial rows conterminous to the preceding tracheids. Later this parenchymatous tissue increases in width, sometimes gradually (fig. 10), sometimes abruptly (fig. 9), and in turn is succeeded by the root tissues proper.

[The Journal for July (29: 479–591) was issued July 30, 1942.]
AMERICAN JOURNAL OF BOTANY, VOL. 29, NO. 8, OCTOBER, 1942.

Examination of serial tangential sections reveals the first-formed parenchyma cells to be in vertical series resembling xylem parenchyma. Generally the fusiform outline of each series of cells is clearly discernible. Further, in radial sections it may be seen that the terminal cells of each series are in line with the upper and lower ends of the preceding tracheids in the same radial row. Such relationships indicate that the parenchyma cells and the conterminous tracheids were derived from the same fusiform initials. These parenchyma cells are soon succeeded by others which tend to decrease in height, to lengthen in the horizontal direction, and to become organized into radial rows (fig. 12).

The relationships described above indicate that the roots originate from sectors of the cambium consisting of variable numbers of fusiform initials and the intervening ray initials. In some instances it appeared that only one or two fusiform initials took part in root formation (fig. 10), but in approximately one-half the sixty-six cases studied the tangential extent of the cambium consumed ranged from four to six cells and in a few instances was as extensive as ten or more cells (fig. 11). The change from a vertical to a radial arrangement in the cells, and the simultaneous vertical contraction and tangential broadening of the parenchymatous tissue in the first-formed parts of the root tissue (fig. 12), suggest that the fusiform initials were subdivided into shorter units, the most centrally located of which increased in number and formed the root meristem.

In some cases a mass of parenchymatous tissue was laid down without root development, as illustrated in the lower part of figure 9. Serial tangential sections of such areas disclosed at some points a succession of cell types in which tracheids were followed by xylem parenchyma with the latter succeeded by tracheids again. Here it would seem that certain derivatives of the fusiform cambial cells were segmented to form the parenchyma cells, but the cambial cells themselves were not subdivided and maintained their shape more or less unaltered through successive divisions. At other points some of the fusiform elements (tracheids and xylem parenchyma) were followed by short cells which in successive sections tended to decrease in number and alter in shape, some being pinched out, others becoming more elongate again. In these cases there was apparently a subdivision of some of the fusiform cambial cells into shorter units. Subsequently certain of these, after brief periods of activity, ceased dividing; whereas others underwent gradual elongation to acquire a fusiform outline again.

Nearly all the parenchyma cells in the first-formed tissues associated with root development had relatively thin walls with little or no lignification. Only

a few sporadic cells were somewhat thicker walled and slightly lignified. As the cells became shorter and tended to lengthen in the radial direction tracheary cells appeared among the parenchyma. The first of these were usually more or less rhomboidal or rectangular in outline with numerous bordered pits on all walls. Toward the exterior the shape became more definitely radially elongated, and the radial and horizontal walls particularly had crowded pits exhibiting various mixtures of alternate and opposite arrangements. These tracheids gradually gave way to the primary xylem in the root proper.

THUJA AND JUNIPERUS.—The development of adventitious roots occurs frequently in *Thuja occidentalis* L., *Juniperus horizontalis* Moench, *J. communis* var. *depressa* Pursh, and when the opportunity offers, in *J. virginiana* L. As described in previous articles (Bannan, 1941 and 1942) the roots connect with peculiar xylem rays which differ from the ordinary rays in their larger size and, especially in *Thuja*, in the more frequent occurrence of tracheary cells. The association between root and ray is illustrated in figure 15. The root meristems apparently are organized from the cambial or adjoining phloem portions of the unusual rays. There was no evidence of fusiform cambial cells being involved as in *Taxus*.

ABIES.—Layering in *Abies balsamea* (L.) Mill. has been reported by Chittenden (1905), Cooper (1911), and Fuller (1913). The layering was noted in trees growing in habitats ranging from deep forest to exposed rocky ridges and mountain tops, but was best developed in the latter types of site. Rooted material examined by the writer was collected from trees growing in the forest and in nearby open areas, such as abandoned fields, which were being invaded. The collections were made in Northumberland County and Parry Sound and Muskoka Districts.

Rooting seemed to occur whenever the branches were buried. In some cases, particularly in the forest, the terminal portions of the branches turned upright and bore lateral branches in whorls so as to resemble small trees. In the open the distal parts of the rooted branches were usually bent only slightly upward and rarely became upright. The roots were scattered without pattern along the lower side of the buried parts of the branches, no aggregation in any particular part of the year's growth being evident (fig. 3).

In all the specimens examined the anatomical relationships between the roots and branches were similar. As shown in figure 13 each root connected inwardly with a radial sheet of parenchymatous tissue which resembled a branch gap and was located above and parallel to a leaf trace.

Fig. 9-17.—Fig. 9-11. *Taxus canadensis*, transverse sections of branch wood showing origin of adventitious roots.—Fig. 12. *Taxus canadensis*, radial section showing origin of root.—Fig. 13. *Abies balsamea*, radial section of branch wood illustrating root trace and subtending leaf trace.—Fig. 14. *Picea Abies*, radial section of branch showing medullary crown and gap associated with dormant bud.—Fig. 15. *Thuja occidentalis*, transverse section of branch wood illustrating unusual ray and connection with adventitious root.—Fig. 16, 17. *Larix laricina*, transverse sections of branch wood showing adventitious roots arising in vicinity of embedded xylem portions of dwarf branches.—Fig. 14, $\times 28$; others $\times 49$.

On the exterior of the distal portions of the branches very small dormant buds were recognized in the axils of leaves at intervals from the tip down as far as the eighth year, below which point they tended to become embedded in and indistinguishable from the bark. Associated with each dormant bud was a connection of parenchymatous tissue extending to the pith and located directly above a subtending leaf trace. The anatomical relationships resembled those described for the roots. It seems clear that the roots arose from dormant axillary buds which were stimulated into activity on being buried and gave rise to roots rather than lateral branches. Although Chittenden (1905) did not cite the evidence upon which his opinion was based, his statement that rooting in layered balsam proceeds from dormant buds is apparently confirmed.

The portion of the root gap nearest the pith was usually composed of parenchyma cells of varied rounded, rectangular or angular shapes. The walls were generally moderately thick and lignified, but here and there were very thin-walled ghost-like cells containing crystals. Oddly, in most cases there was no protoxylem associated with the part of the gap nearest the pith. Only in a few instances did small strands of spiral or scalariform tracheids extend along the bottom or sides of the gap and connect with the protoxylem in the main branch. Farther out the gap tended to contract vertically and to widen tangentially, the shape changing from narrowly oval in tangential section to round. The parenchyma cells became more regularly arranged in horizontal (radial) rows and tended to be definitely elongated in that direction. Beginning usually in the second or third annual rings there was a noticeable increase in the number of tracheids associated with the parenchyma cells. These tracheids were generally relatively short, and many were curved or bent so as to resemble the so-called "arm-pit" tracheids found along the under side of leaf traces. The tracheids as a rule were pitted, but had reticulate or irregular spiral thickenings on the inner side of the walls. Toward the exterior these tracheids became more numerous and ultimately more or less completely ensheathed the parenchymatous tissue in the center. In the succeeding growth rings there was no appreciable increase in size until the root was initiated, whereupon secondary tissues were added. In the specimens studied the time of root formation varied from the eighth to the seventeenth years.

As described above a striking feature of the root gaps was the absence or feeble development of accompanying protoxylem tissue. Traces were indistinguishable or of small size, consisting at the most of only a few spiral or scalariform tracheids. Similar conditions obtained in the case of the smallest lateral branches, but the larger branches, especially those at the upper end of the year's growth, generally had wide gaps with numerous traces extending along the base and sides of the gap.

PICEA.—Layering in *Picea mariana* (Mill.) BSP. has been reported by Cooper (1911) both for trees

growing in the forest and in bogs, and by Fuller (1913) for trees in exposed rocky areas. Cooper reported the habit for *P. glauca* (Moench) Voss on nearly bare rocks, but Fuller was unable to find many instances of rooting in this species.

Most of the material studied by the writer was black spruce collected from bogs in the Parry Sound District. The more widely spaced trees had branches to the ground, the lowest branches usually being bent so that their median portions were buried in the sphagnum or débris. These buried parts were generally rooted. In most cases the distal portions of the branches turned only slightly upward; seldom did they become upright to produce the "hen and chickens" appearance described by Fuller (1913). Much more difficulty was experienced in finding rooted branches of *Picea glauca*. A wide area of Renfrew and Lanark Counties in eastern Ontario was scouted, but very few instances of rooting were discovered. Although many trees had branches to the base, these were rarely covered by soil and hence little opportunity was provided for rooting.

In *Picea mariana*, unlike *Abies balsamea*, the roots were generally located in close proximity to the terminal bud scars (fig. 4), a distribution noted by Cooper (1931) in *Picea sitchensis*. As shown in figure 4 at (a), (b), and (c) most of the roots were situated immediately above or distal to the terminal bud scars; less often they were short distances below, as at (e); and in only a few instances were they distributed elsewhere along the branch as at (d). Sectioning of the wood showed that the roots located close above the terminal bud scars arose from the main branch, whereas the majority of those below, as at (e) in figure 4, originated not from the principal branch but rather from embedded basal portions of lateral branches whose distal parts had been cast off. This association is illustrated in figure 5. Here the root (a) arose from a lateral branch (b), connecting with it close above a crown of thick-walled cells (c) in the pith. This crown is a layer of cells separating the mature part of the old growth from the young tissues of the bud which later gave rise to the lateral branch. The lateral branch died, the distal part was exfoliated, and only the basal portion remained and gradually was surrounded by the secondary xylem of the principal branch. The relationship between the root and the lateral branch was thus similar to that between such roots as shown at (a), (b), and (c) in figure 4 and the main branch. In all these cases the roots were initiated in the basal part of the year's growth.

Lewis and Dowding (1924) have shown for *Picea glauca* that the position of the terminal bud is marked in the pith by a crown of thick-walled cells. Above the crown the pith cells are in regular longitudinal rows; below they are disordered and often more or less broken down to form a cavity. Similar terminal diaphragms of thick-walled cells were observed in *P. mariana* and *P. Abies* (fig. 14). In nearly all layered branches studied the roots connected inwardly with parenchymatous tissue extend-

ing to the pith close above such medullary crowns, the association resembling that illustrated in figure 14. The relationships between the root gaps and crowns were generally similar, whether the roots arose from the principal or from the basal parts of embedded lateral branches. In only a few instances, where the roots originated in the central part of the year's growth some distance from the terminal bud scars, were the root gaps subtended by leaf traces as in *Abies*.

Examination of the exterior of the distal portions of branches revealed the presence of small dormant buds close above the terminal bud scars. In radial sections it was seen that these buds connected with parenchymatous gaps located directly above the medullary crown (fig. 14). The dormant buds thus had the same anatomical relationships as the roots on the layered branches.

Although the roots in *Picea*, as in *Abies*, evidently arose from dormant buds,² the distribution of the roots was quite different in the two genera. In *Abies* the roots were distributed along the branch and, as a rule, were not associated with the terminal buds; in *Picea* they were usually located immediately above the terminal bud scars. In *Abies* the root gaps were subtended by leaf traces; in *Picea* the gaps were nearly always found close above medullary crowns, rarely some distance away and associated with leaf traces as in *Abies*.

As in *Abies* the portion of the root gap adjoining the pith was composed of variously shaped parenchyma cells. Most of these were thick-walled, but a few were thin-walled and contained crystals. Toward the exterior the cells became more uniformly elongated in the radial direction, and their arrangement became more compact. In some cases no protoxylem tracheids could be discerned accompanying the part of the gap nearest the pith. In other instances small traces extended along the bottom or sides of the gap and connected with the main system in the branch. From the second or third year outward a considerable development of "arm-pit" tracheids took place, and eventually these more or less ensheathed the centrally located parenchyma cells. So long as the bud remained dormant there was no appreciable increase in the diameter of the trace complex, but with development of the root secondary xylem was added.

In most instances the buds which developed into lateral branches had larger and more numerous primary vascular strands than the dormant buds. In general the largest and best vascularized buds were located toward the upper end of each year's growth, and these buds usually produced the most vigorous lateral branches. Downward the buds tended to decrease in size and to have less extensive primary vascular systems. A noticeable reduction in size of the lateral branches developing from these buds was

²In some hormone-treated cuttings of *Picea Abies* kindly sent the writer by Dr. N. H. Grace most of the roots arose at the cut end of the branches, the origin differing from that observed in the uninjured layered branches described above.

also apparent. Toward the base of the year's growth the buds were poorly vascularized, many having no discernible protoxylem, others only very small traces. These buds generally remained dormant, unless stimulated to growth by some unusual circumstances such as the burial of that part of the branch, whereupon they produced roots.

LARIX.—*Larix laricina* (Du Roi) Koch growing in bogs along with black spruce has been reported by Cooper (1911) as layering abundantly. In most of the swamps visited by the writer, however, the lower branches of the larch trees were dead and unrooted. The only rooted specimens discovered were growing in dune areas near the shores of lakes. At Presqu'Île on Lake Ontario a few widely spaced trees whose lower branches had become covered by shifting sand were layered, and similar material was obtained for the writer by Dr. Kathleen and Mr. Donald Hull from Inverhuron Beach on Lake Huron.

Nearly all the roots on the layered branches arose in close proximity to dead dwarf (leaf-bearing) branches. Sometimes no trace of the dwarf shoot remained on the exterior (fig. 6) but here sectioning of the branch revealed the basal portion of a dwarf branch buried inside. The number of roots associated with each dwarf branch varied greatly. Sometimes there were one or two moderately large functioning roots and a circlet of small poorly-developed roots which failed to grow appreciably in length (fig. 7 and 8); occasionally there were only a few rudimentary roots (fig. 8); and in other cases only one or two large roots were formed (fig. 6).

The total number of rooted specimens found was not great, and the relationships between the roots and the dwarf branches were not precisely similar. In some instances the roots were connected with the end or sides of the xylem core of the buried part of the dwarf branch (fig. 16 and 17). In another case the dwarf branch apparently was broken off relatively early and the roots arose from the wound calus covering the injury. In yet another instance the roots grew out from the secondary xylem of the main branch surrounding the dwarf branch. Since none of the specimens studied showed the earliest stages of development, one can only speculate on the nature of the cells which formed the root meristems. It seems most probable that the latter were organized from the cambium or recently formed undifferentiated tissue adjoining the dwarf branch.

PINUS AND TSUGA.—The writer is aware of only one reference in the literature to layering of pine in America. Lutz (1939) reported a single instance in *Pinus Strobus*. Rooting of hemlock branches has been described for *Tsuga Mertensiana* by Lutz (1930), and for both western species, *Tsuga Mertensiana* and *T. heterophylla*, by Cooper (1931). In Ontario the writer was unable to find layering in any of the native species of pine or hemlock (*Pinus Strobus* L., *P. resinosa* Ait., *P. Banksiana* Lamb., or *Tsuga canadensis* (L.) Carr.). The habit of the trees was usually such as to make layering impos-

sible, but even in pine plantations where the lower branches were sometimes in contact with the ground no roots were discovered.

SUMMARY

Certain anatomical features of the origin of adventitious roots in the native Ontario conifers were studied from layered material collected in different parts of the province.

In *Taxus canadensis* the roots arose from sectors of the cambium comprising variable numbers of fusiform initials and the intervening ray initials. The tangential extent of the cambium involved ranged from one to more than ten cells.

In *Thuja occidentalis*, *Juniperus communis* var. *depressa*, *J. horizontalis*, and *J. virginiana* the roots were conterminous to unusual xylem rays which differed from the ordinary rays in their larger size and, especially in *Thuja*, in the higher proportion of tracheary cells. The root meristems apparently origi-

nated in the phloem or cambial portions of these rays.

The roots in *Abies balsamea*, *Picea glauca* and *P. mariana* arose from dormant buds, but the distribution of the buds differed in the two genera. In *Abies* the roots were distributed irregularly along the layered branches, in *Picea* they were usually restricted to the neighborhood of the terminal bud scars.

In *Larix laricina* the adventitious roots originated in the vicinity of dead or injured dwarf branches. Layering was not discovered in *Tsuga canadensis* or in *Pinus* spp.

Examination of a few hormone-treated cuttings (*Picea*) indicated a different type of root origin from that described above for layered specimens.

THE EXTRACTION OF AUXIN FROM PLANT TISSUES. II¹

Kenneth V. Thimann, Folke Skoog, and Ava C. Byer

IT WAS shown in an earlier communication (Thimann and Skoog, 1940) that the bulk of the auxin in *Lemna* is present in a bound form, from which it is liberated slowly by long standing with ether. The extreme slowness of the extraction is not due to low solubility of auxin in the solvent, but is conditioned by the conversion of the auxin from an inactive to a free form. The evidence for this is: (1) the rate of liberation is independent of the volume of solvent used, (2) extraction is not hastened by maceration, (3) extraction is not hastened, but the liberation is actually prevented, by boiling, and (4) the presence of water is essential for the extraction process. In boiled material the bulk of the activity is lost and cannot be recovered however much the extraction period is prolonged; in dried material, on the other

hand, the subsequent addition of water allows recovery of a considerable part of the activity (in the case of *Avena coleoptiles*, all of the activity). It was deduced that the auxin is in some way combined with a protein, or a protein-like material, from which it is set free by hydrolysis. Support for this deduction was obtained by experiments, briefly reported, in which the extraction was greatly hastened by proteolytic enzymes (Skoog and Thimann, 1940).

Some trials with representative growing tissues indicated that the existence of such an auxin complex is of very general occurrence. As a matter of fact, evidence that auxin may exist in inactive bound form was given some time ago by Kögl, Erxleben, and Haagen-Smit (1934) when they showed that activity could be obtained from salad oil by treatment with lipase or by hydrolysis with acid. Re-

¹ Received for publication May 6, 1942.

Fig. 1-2.—Fig. 1 (above). Dried *Lemna* powder (0.3 g. samples) incubated with and without 3 mg. of enzyme at 37° and pH 8.5 for twenty-four hours, then brought to pH 4 and given successive ether extractions in icebox. Begun May 4, 1940.—Fig. 2 (below). Two different con-

cently also Avery, Berger, and Shalucha (1941) have shown that the auxin in corn endosperm is set free by alkaline hydrolysis. It would appear, however, that the state of auxin in corn endosperm is entirely different from that in green tissues, investigated in our earlier experiments. Clear-cut evidence for this will be given below.

The present paper presents further evidence as to the nature of the auxin complex and brings out certain important considerations which will have to be taken into account before a reliable and convenient method for the quantitative extraction of auxin from plant tissues can be achieved. The standard *Avena* test was used throughout, and other procedures were as described earlier (Thimann and Skoog, 1940). All yields are expressed in the same arbitrary units as were used in the preceding paper, which are equivalent to fifty plant units.

EXPERIMENTS WITH ENZYMES.—Because of the indications, summarized above, that the material to which the auxin is bound may be of protein nature, experiments with proteolytic enzymes were undertaken.

Lemna, grown as previously described, was dried in a rapid current of warm air and ground to a fine powder. Samples of this powder were then wetted and incubated with varying amounts of proteolytic enzymes, the mixture being adjusted to the optimum pH of the enzyme with HCl and Na₂CO₃. Several temperatures between 25° and 50°C. were used, the periods of incubation being from one to five days. The solutions were afterwards acidified to about pH 4 (colorimetric) and then kept under ether, freshly distilled from FeSO₄, in the icebox. At intervals over a period of many months the ether was removed and renewed and the activity in the ether extracts determined as previously described. In preliminary experiments, crystalline trypsin and chymotrypsin (Kunitz and Northrop, 1935),² especially the latter, proved to be effective. Ficin (Walti, 1938) was less so, while papain, both with and without activation by HCN, was apparently inactive. Chymotrypsin was, therefore, selected for more extensive study.

The results of four comparable experiments are presented herewith. Two are given as figures 1 and 2, and two others as tables 1 and 2. Each point on the curves, or each figure in the tables, represents the best value for that particular extract as deduced from a number of *Avena* tests done at different dilutions. The total maximal yield varies with the particular sample of *Lemna* used, the extreme limits being usually 1,000 and 3,000 units per gram fresh weight (cf. Thimann and Skoog, 1940, p. 952), though the experiment of figure 1 is considerably

² The chymotrypsin preparation, obtained originally from Dr. Kunitz, was kindly supplied by Dr. A. A. Abramowitz.

concentrations of chymotrypsin (CT). Dried *Lemna* powder, 0.3 g. samples, incubated twenty-four hours at 37° and pH about 8.5, then brought to pH 4 and extracted with ether. Begun May 21, 1940.

TABLE 1. *Effect of chymotrypsin on extraction of auxin from Lemna. Dried powder, 0.3 g. samples (equal to 3 g. fresh weight), incubated with enzyme solution at pH 8.5 and 37° for twenty-four hours, then acidified. Extractions in icebox.*

Total	508	3,986	9,157	9,554

lower. The results show firstly, that in all experiments the yield of active auxin is greatly increased by the enzymes used. Secondly, in three of the four experiments shown, this increase takes place mainly in the earlier extractions. In later extractions the rates of liberation are slow and the controls may in some cases equal the rates in the enzyme-treated samples (see the last six extractions of table 2), while in other cases (table 1) the enzyme-treated samples show higher rates of liberation over the whole period. The slowness of liberation in later extractions is of course partly due to the fact that pH 6 and icebox temperature are far from optimal conditions for chymotrypsin. Thirdly, the time at which the rate of liberation decreases markedly is nearly the same with or without enzyme. This may be seen in figures 1 and 2 and also in table 2, in which after October 18 the activity of the enzyme seems exhausted. This result is surprising, since the added enzyme might be expected to set free rapidly what the control material could have set free slowly. This could be explained in two ways: (a) the added enzyme acts upon some additional source of auxin which was not liberated at all in the controls, (b) the bound auxin complex deteriorates with time in some way so that liberation becomes increasingly

difficult. The latter view is somewhat supported by the fact that dried *Lemna* powder on prolonged keeping loses a large part of its total extractable auxin. The general similarity in the shapes of the extraction curves with and without added enzyme is strong support for the view that the liberation of auxin in the controls is itself enzymatic.

The data previously reported (tables 4, 5 and 6 of Thimann and Skoog, 1940) show clearly that boiling prevents the subsequent slow liberation of auxin from *Lemna*. This effect of boiling may be merely the destruction of the enzyme, or it may be destruction of the auxin complex itself. If it is the former, it might be possible to liberate the auxin from boiled material by adding proteolytic enzymes. Accordingly, samples of the powder were boiled for five minutes in water and then treated with chymotrypsin as before. The results of one such experiment are shown in figure 3. This experiment was carried out at the same time as the experiment of figure 2. At the end of the third extraction, after which practically all the auxin had been removed from the boiled material, the unboiled control had yielded a total of 1,176 units, while the boiled sample treated with chymotrypsin had given 1,455. Thus chymotrypsin added to the boiled material has raised the

yield to a value even higher than that of the unboiled control. It will be seen from the curve that later extractions continued to set free appreciable amounts (some 200 units) in presence of chymotrypsin but practically none in the plain boiled control. (The unboiled control in the same period, however, yielded about 1,000 additional units.) Thus the enzyme added at the start of the experiment continues to exert a definite though small effect over a long period of time. It may be concluded that, at least in part, the added proteolytic enzyme can replace the agent which is inactivated by boiling. However, since the total yield is only about one-fourth³ that set free by chymotrypsin from unboiled material in the same experiment, the second possibility, *i.e.*, that the auxin complex has been irreversibly changed, is by no means excluded. It is of interest to note that according to Gustafson (1941), the free auxin is not inactivated by brief boiling.

INFLUENCE OF ENZYME CONCENTRATION.—In an attempt to obtain optimum yields, the influence of the concentration of enzymes was studied. It will be noticed in figure 2 that of the two concentrations of chymotrypsin used, the lower showed the greater activity, at least at first. The same is seen in tables 1 and 2, but here the higher concentration gradually recovers the lead to reach about the same final value. This effect was found consistently and indicates that for some reason there is an optimum concentration of chymotrypsin. A more careful study of this factor is shown in figure 4. In this experiment the enzyme preparation, which is rich in $MgSO_4$, was dialyzed against distilled water before use, but this treatment seems to have had very little effect. The results show excellent proportionality between auxin liberated and enzyme concentration up to a well-marked optimum at 0.5 mg. per cc. The reason for this optimum has not been investigated, but incidentally it affords evidence that the enzyme preparation does not itself supply any auxin. This confirms negative auxin tests on three samples of enzyme, both freshly prepared and after incubation as above.

Results of a similar experiment with crystalline ficin (Merck) are given in table 3. Again there is a good indication of proportionality with enzyme concentration, and a clear-cut optimum. The ficin alone contained no auxin.

THE INFLUENCE OF TREATMENT FAVORING ACTION OF AUTOGENOUS ENZYMES.—In view of the above results with added enzyme, attempts were next undertaken to hasten the auxin-liberating activity of en-

³ In another experiment the ratio was one-third.

Fig. 3-4.—Fig. 3 (above). As figure 2, but *Lemna* powder boiled ten minutes in water before addition of enzyme. (The rise in extracted auxin in the unboiled control after sixty-two days is unexplained.) Begun May 21, 1940.—Fig. 4 (below). Effect of different concentrations of chymotrypsin (CT), dialyzed for twenty hours before use. Dried *Lemna* powder, 0.1 g. samples, incubated forty-eight hours at 37° and pH 8.5, then brought to pH 4 and extracted with ether. Three days for first extraction. Total yield based on subsequent extractions over six months in icebox. Begun October 5, 1940.

TABLE 3. *Liberation of auxin by crystalline ficin. Dried Lemna powder, 0.1 g. samples (=1.0 g. fresh weight), incubated forty-eight hours at 29° and pH 5 with the enzyme, then extracted with ether in icebox for three days, and a further four days.*

zymes presumably present in the plant tissue itself. This was done by prolonged incubation of the moist plant material at a favorable temperature. In the first experiments of this type, enormous but very variable yields were obtained, values as high as 40,000 units per gram of *Lemna* (as compared with the normal figure of 1,000 to 3,000) being reached. Associated with this was the presence of a large population of bacteria. Frequently, the high yields were correlated with the total bacterial population as determined by counts on nutrient agar plates. On the other hand, an occasional high bacterial count was associated with a very low yield, so that it is evident that bacterial contamination can both produce and destroy auxin. Clearly, successful incubation requires aseptic or at least antiseptic conditions. Using plate counts in parallel with auxin determinations, a large number of antiseptics was studied, but in the few cases where these were completely effective in stopping bacterial growth, the presence of the antiseptic interfered seriously with the subsequent auxin tests.

A few experiments with *Lemna* which had been grown in bacteria-free culture, prepared and incubated under aseptic conditions, and checked for sterility afterwards by bacterial counts, gave inconclusive results and will not be reported in detail. Since this method would in any case not be of general application for the determination of auxin, it seemed preferable to concentrate attention upon the use of antiseptics. Of these, phenol was the only one which completely suppressed bacterial growth and

at the same time gave consistent figures for auxin content. A serious disadvantage of the use of phenol is that it causes extensive destruction of the auxin. This is true even when pure phenol is incubated with pure indole-acetic acid and the solution afterwards extracted with ether, as is shown by table 4. Never-

TABLE 4. *Destructive effect of incubating pure indole-acetic acid with phenol. All vessels brought to pH 3 before extraction. Each figure the mean of two samples.*

theless, although the yields obtained are much less than the true total auxin, this method does at least allow a demonstration of the effects of incubation and of added enzyme. In the two experiments of table 5 fresh *Lemna* was suspended in 2 per cent phenol. The figures show that auxin is steadily liberated with increasing time of incubation. As might be expected, 30° is more effective than 50°.

As a matter of fact, very similar results both qualitatively and quantitatively were obtained in several experiments in which appreciable bacterial contamination did not occur. In the two experiments

40°	5 days	2%	0.1	118	239

summarized in table 6, phenol was not added. It is clear that both with and without added chymotrypsin, the yield of auxin is increased considerably by incubating at 30°, and to a less extent at 50°. In experiments with phenol, auxin does not continue to appear after the first two or three extractions (see table 5), although the phenol has been entirely removed in the first ether extraction. This may indicate a destructive effect on the auxin reserves in the tissue.

The experiments are in the main thoroughly consistent with the view that the normal liberation of auxin from *Lemna* kept under ether is enzymatic, but unfortunately they do not prove it conclusively. There is apparently a purely physical effect of incubation on the liberation of auxin. In one experiment a slight but definite increase was obtained on incubating sterile and autoclaved *Lemna*. A clear-cut decision on this point has not been reached and much more extensive experimentation would be required to do so.

Results similar to those with *Lemna* were obtained on leaves, using *Nicotiana tabacum*, grown in the greenhouse (table 7). Fresh leaves, cut into medium sized pieces, were incubated two to five days with and without enzyme. The experiment shows again

that, although phenol causes some destruction, incubation with chymotrypsin even in the presence of phenol greatly increases the yield of free auxin.

GENERAL CONSIDERATIONS OF THE SERIAL EXTRACTION METHOD.—In all our experiments it has been clear that complete extraction can only be obtained by very numerous serial extractions spread over a long period of time. In every extraction there is a risk of some loss; it was, therefore, important to determine whether the extraction procedure in itself destroys any auxin. The following data show that it does.

In the first place, there is a general tendency for the yield per gram of *Lemna* to be greater with large than with small samples. This in itself is suggestive but not conclusive. In the second place, however, direct experiments in which two duplicate samples were extracted, one frequently and one infrequently, show that the total yield is considerably greater in the latter. One such experiment is given in table 8.

A similar loss by frequent extraction was shown in an experiment carried out with the alga, *Ulva lactuca*, freshly collected from the shore. Auxin contents of some marine algae have been reported by van der Weij (1933) and van Overbeek (1940),

using a single extraction or a short-time Soxhlet extraction with ether, and by duBuy and Olson (1937) using a single extraction with chloroform. Our figures are given here (table 9), because they show that also in this material the general process of auxin liberation closely resembles that in the leaves of higher plants, and determination of total auxin can only be made by prolonged extraction. It will be seen from the first series that a period of about eight

weeks in the icebox is required to obtain 75 per cent of the total yield. The second series shows that, as with *Lemna*, a few extractions, widely spaced, give higher yields. This is mainly true in the first eight weeks while the amount of auxin is still considerable. It must, unfortunately, be concluded that each extraction causes appreciable loss of total activity.

These considerations suggest that a first approximation to the determination of total auxin can be

TABLE 10. Tomato leaves. Matched samples. Dry material extracted with ether thoroughly dried over sodium in all cases; fresh material extracted with moist ether. See text.

had by covering the fresh material with peroxide-free ether, leaving it in the icebox for about eight weeks, and determining the auxin in the ether extract and washings. After covering the material with fresh ether, a second extraction should be made a few weeks later. The sum of these two extractions will in most instances add up to at least 75 per cent of the total extractable auxin. Reference to table 11 of the previous publication (1940) will show that this procedure will probably suffice for roots, while the controls of figures 2 and 3 above show the same thing for *Lemna*, and the controls of table 10 for leaves.

Another important influence is that of water. It was shown in Part I (1940) that, in *Avena* coleoptiles and roots as well as in *Lemna*, thorough drying prevents the extraction of auxin by ether. On adding water, auxin may again be extracted. In these experiments, the ether extract from the dry material was freed from ether and taken up in aqueous agar in the usual way. Subsequently, however, it was stated by Link (1940) that this ether may contain a precursor from which auxin is set free by simple warming with water. This was not confirmed (Link, Eggers, and Moulton, 1941), and the experiment below shows also that it is not the case; water sets free nothing from the ether extract. From the dried *Lemna* itself, however, water sets free extractable auxin in the usual way. This confirms (if further confirmation be needed) the necessity of water for the extraction process.

The experiment was as follows: Fresh *Lemna* (15 g.) was thoroughly washed, dried first in a stream of hot air and then overnight in the oven at 50°, and then extracted for eight days with thoroughly dry ether (freshly distilled over sodium). The ether extract was divided into two equal parts, both evaporated to dryness, and the residue of one part (b) gently warmed with water. Subsequently both (a) and (b) were taken up in agar and tested. To 0.5 g. of the residual dry *Lemna* (corresponding to 5 g. fresh material) 0.5 cc. water was added and the moist product again extracted with ether (c).

(a) activity of dry ether extract of dry *Lemna*.... 0 units
(b) same, after reacting with water..... 0 units
(c) ether extract of moistened *Lemna*..... 50 units

Although all our experiments on *Lemna* and *Avena* agree in showing the necessity of water for auxin extraction, experiments with leaves are not always consistent. Thus Went (private communication), in repeating our experiments with tomato leaves, actually obtained more auxin from dried than from fresh material. Section A of table 10 shows a similar result. Though wetting appears to release some more auxin, the dried material yields more than the fresh. In these experiments the leaves were dried in a current of warm air for thirty-six hours, followed by an overnight stay in the oven at 40°. If the liberation of auxin is enzymatic, such a protracted exposure to warmth while still moist would allow extensive liberation. It would also allow the development of microorganisms.

After numerous attempts to hasten the drying, it was found that if the leaves were first frozen in solid CO₂ they could subsequently be dried in a few hours instead of requiring two days (cf. also Link, Eggers and Moulton, 1941). Section B of table 10 shows that such leaves, frozen and then quickly dried, behave in the manner found in all our earlier experiments. Only traces of auxin are extracted while the material remains dry. On adding water the yield increases, but does not reach that of the fresh material. Drying, in other words, causes a considerable permanent inactivation of the auxin. In such experiments it must be noted that dried ether will undoubtedly absorb water in the icebox, even in a closed vessel. Section C of table 10 presents a similar experiment; although the data from material dried slowly are not clear, the contrast between fresh and rapidly dried leaves is perfectly definite, and the subsequent addition of water has the expected effect. The figures for heated material are included for completeness; they serve only to confirm for leaves the previous findings on other material that heating almost completely prevents the extraction of auxin.

In general it can be concluded that leaves do not differ in principle from the other material studied, though they are more difficult to dry, and perhaps more sensitive to small amounts of water.

COMPARISON WITH CORN ENDOSPERM.—The ready liberation of auxin from corn endosperm by alkaline autoclaving (Avery, Berger, and Shalucha, 1941) contrasts sharply with the behavior of *Lemna*, in which all our experiments have shown that heating to 100° at any pH produces only destruction of the auxin. To make this point clear, a comparative experiment was carried out in which the endosperm and *Lemna* were given the same treatments side by side.

A sample of dry field corn (Yellow Dent), freed from the embryos, was ground in a ball mill and three pairs of duplicate 0.5 gram samples treated as follows:

- (1) Extracted for three days with 5 cc. H₂O.
- (2) Brought to pH 9 with dilute NaOH, autoclaved thirty minutes at 120°.
- (3) Extracted for three days with moist ether in presence of a few drops of dilute acetic acid.

In the first two pairs, the water extract, after filtering, washing and bringing to pH 4, was tested directly; in the third the ether was evaporated off

TABLE 11. Comparison of *Lemna* powder with corn endosperm. Each figure is the mean of two 0.5 g. samples. For details see text.

Treatment	Auxin units extracted	
	Corn endosperm	<i>Lemna</i> powder
Extracted with water	380	0
Autoclaved at pH 9, then cooled and acidified	7,080	0
Moistened and extracted with ether	291	92

and the residue taken up in 0.5 cc. warm agar in the usual way. Dried *Lemna* powder (paired 0.5 g. samples) was treated in the same three ways. The results are given in table 11. It is clear that in the corn, water treatment extracts even more auxin than ether (as was shown by Avery, Creighton and Shalucha, 1940), and alkaline autoclaving increases the yield some 2,000 per cent. In *Lemna*, water does not extract any detectable auxin and alkaline autoclaving has no effect, while ether will extract a considerable amount. The contrast is complete. It may be noticed also that, although no attempt was made to obtain the maximum yield, the absolute amount of auxin obtained in the autoclaved corn is comparable with that found by Avery, Berger and Shalucha, for our units are equivalent to fifty plant units, and since one-half gram samples are used, our figure should be multiplied by one hundred to give total plant units, and by a further factor of four to give "total degrees curvature" of these authors' notation. The value is thus some three-quarters of a million plant units, or three million "total degrees curvature," per gram.

SUMMARY

The yield of auxin from *Lemna* is increased greatly by short incubation with chymotrypsin or trypsin. Ficin has a similar, though smaller effect.

The same is true for leaves of tobacco.

Although the yield is very greatly decreased by boiling, treatment with proteolytic enzymes raises the yield from boiled material to a value comparable with that obtainable from the unboiled.

It is concluded that the auxin in green material is bound to protein or a protein-like substance, and that the effect of boiling, while it may to some extent destroy the complex itself, is in the main to destroy the enzyme system which liberates the auxin.

On the other hand, prolonged incubation of plant material to allow the autogenous enzymes to liberate the auxin is not a practicable general procedure for determination of total auxin, on account of the large and variable production of auxin by bacteria. Addition of bactericides cannot completely overcome this difficulty.

Incubation of plant material, or of pure indoleacetic acid, with phenol leads to extensive destruction of the auxin activity. In spite of this, some auxin-liberating action of enzyme occurs even in phenol.

Ulva lactuca, a green alga, behaves like the leaves of higher plants in that its auxin is liberated to ether only with extreme slowness.

Tomato leaves are shown to behave like the materials previously studied in that water is necessary to allow the extraction of auxin, provided only that the leaves are dried rapidly. During slow drying, auxin may in some cases be produced, either by bacteria or by enzymatic liberation.

In serial extractions with ether, each extraction destroys a part of the auxin which has been liberated.

Unlike corn endosperm, no auxin is liberated from *Lemna* either by extraction with water or by alkaline autoclaving. The bound forms of auxin in these two plant materials are, therefore, of quite different types.

Suggestions for a simplified procedure are put forward which will determine the bulk of the total auxin in green plant material with a minimum number of extractions.

WHEN BOILED grass leaves are used as bait for the saprophytic chytrids in soil and water collections, *Pythium* is often found growing on the grass leaves. This method of collecting has proved effective in obtaining a number of species of *Pythium* and parasites of *Pythium*, which frequently are species of *Pseudolpidium* or *Olpidiopsis*. *Pseudolpidium gracile* Butler, the resting bodies of which lack companion cells, has been recollected and studied. In addition, two new species of *Olpidiopsis*, the resting bodies of which possess companion cells, have been found parasitizing *Pythium*. In a number of collections, however, the grass leaf bait yielded a species of *Aphanomyces* which was parasitized by what appeared to be *Pseudolpidium Aphanomyces*, in that all the resting bodies were without companion cells. These four species of *Pseudolpidium* and *Olpidiopsis* will be discussed in this paper.

Recently taxonomic studies of the genus *Olpidiopsis* have been published by Shanor (1939, 1940) and McLarty (1939, 1941). Shanor (1939) suggests that the genus *Pseudolpidium* should be combined with *Olpidiopsis* for "none of the species originally placed in the genus when it was established can remain unquestionably as *Pseudolpidium* species. The continuance of the genus seems to rest on only two species, *P. Pythii* and *P. gracile*, both described by Butler. Even these two species need further critical study." McLarty (1941) merges the genus *Pseudolpidium* with the genus *Olpidiopsis* and amends *Olpidiopsis* "to include species with smooth and spiny zoosporangia which may form either sexual or asexual spores." Of *Pseudolpidium Pythii* and *P. gracile* McLarty states, "Very little is known of these species, although each has been observed since Butler's time. The resting spores of these species, as they are illustrated in the literature, appear very similar in appearance to spiny zoosporangia. Until they are re-collected and critically examined, these species may be transferred to *Olpidiopsis* as strictly asexual species."

No opinion is expressed here as to the validity of the genus *Pseudolpidium*. The combining of *Pseudolpidium* and *Olpidiopsis* by McLarty (1941) on the basis of his having found both sexual and asexual spores in monospore cultures of his species, *Olpidiopsis Achlyae*, is justifiable. Nevertheless, the studies presented in this paper will emphasize the fact that in certain forms, formerly considered as species of *Pseudolpidium* and now to be placed in *Olpidiopsis*, according to McLarty, the lack of a companion cell on the resting spore is a constant and consistent characteristic of the species. In this connection two species, *Pseudolpidium gracile* Butler and *P. Aphanomyces* (Cornu) Fischer are now to be discussed.

This work was supported by a grant from the Penrose Fund of the American Philosophical Society.

Pseudolpidium gracile Butler.—A soil collection made by Dr. H. R. Totten at Key Largo, Florida, on December 27, 1940, yielded *Pythium rostratum* (fig. 15-20), parasitized by a species of *Pseudolpidium* (fig. 7 and 8). Because of the length of the spines and the yellowish color of the resting bodies, the parasite was identified as *Pseudolpidium gracile* Butler, though Butler (1907) lists *Pythium rostratum* as the host of *Pseudolpidium Pythii*. *Pythium intermedium* is given as the host of both *P. Pythii* and *P. gracile*, so it is possible that *Pythium rostratum* is likewise susceptible to both species of *Pseudolpidium*. *Pseudolpidium gracile* has been kept under observation in culture on its host since the date of its collection. Resting bodies are constantly produced in large numbers, but not a single resting body with a companion cell has been seen. The resting body is yellowish in color and covered with slender spines which attain a maximal length of 4 μ (fig. 3). In shape the resting body varies from spherical to oval and measures 12 to 27 μ in diameter, exclusive of the spines. Butler states that the wall of the resting body of his species is rather thin and in his figures of the resting body the wall does appear to be very thin. It is for this reason that Shanor and McLarty have suggested that what Butler figures as resting bodies may be only spiny-walled zoosporangia. It is possible that Butler drew the resting bodies before the wall had attained its mature thickness for the contents of the resting body as illustrated by Butler appear to be undifferentiated. A mature resting body from the cultures of our *P. gracile* contains a single central oil globule surrounded by a peripheral layer of vacuolated protoplasm (fig. 3). Butler does not give any measurements of the thickness of the exospore and endospore walls of the resting bodies of *P. gracile* but measurements made on the resting bodies in our cultures show that the endospore may attain a thickness of 0.7 to 1.2 μ while the exospore varies from 1.7 to 2.5 μ in thickness.

The development of the zoosporangia and the discharge of the spores do not differ from the descriptions of Butler. A period of vacuolization, during which one or two exit papillae appear on the sporangium, is terminated by the sudden disappearance of the vacuoles. Very soon after the disappearance stage the spores are cut out and discharged. The zoospores are biflagellate. The walls of some of the zoosporangia in older cultures are often covered with very short, fine spines (fig. 9).

Pseudolpidium Aphanomyces (Cornu) Fischer.—A culture of *Aphanomyces cladogamous* Dreschler was obtained from soil collected by Philip Couch near Petahatche, Mississippi. The *A. cladogamous* was parasitized by a species of *Olpidiopsis* which formed resting bodies that lacked companion cells (fig. 4 and 24). The identification of this species constitutes a difficult problem for two species of

Pseudolpidium or *Olpidiopsis* have been reported as parasites of *Aphanomyces*. *Olpidiopsis luxurians*, described by Barrett (1912) and restudied by

Shanor (1939), is a well defined species, having companion cells on the resting bodies, which parasitizes *Aphanomyces laevis*. *Pseudolpidium Apha-*

nomycis (Cornu) Fischer was described by Cornu (1872) as a species of *Olpidiopsis* even though he had found only the zoosporangia in an unidentified species of *Aphanomyces*. Fischer (1892) transferred this species to *Pseudolpidium* without having observed the resting bodies. Subsequently, Dangeard (1891) illustrated a resting body without a companion cell that he found parasitizing *Aphanomyces*, and Petersen (1910) described resting bodies with companion cells in the hyphae of a species of *Aphanomyces*. McLarty (1941) would combine the parasites of *Aphanomyces* observed by Cornu, Dangeard, and Petersen under Cornu's original name, *O. Aphanomyces*. It is not possible to know whether Cornu described as *O. Aphanomyces* the zoosporangia of *O. luxurians*, the present species, or some other form of *Olpidiopsis*. Yet it seems preferable now not to describe a new species of *Olpidiopsis* on *Aphanomyces* but to recognize the form on *A. cladogamous* as *Olpidiopsis Aphanomyces* Cornu.

OLPIDIOPSIS APHANOMYCIS Cornu

Pseudolpidium Aphanomyces (Cornu) Fischer

Zoosporangia 34.2 to $94.05\ \mu$, one or two, sometimes more in swellings of the host hyphae which are usually unilateral. Zoospores biflagellate. Resting

bodies oval, $24.6 \times 28.7\ \mu$ to $36.9 \times 43.05\ \mu$, or spherical, 13.2 to $44.46\ \mu$, covered with broad-based spines, 2.1 to $4.1\ \mu$ in length; exospore wall $4.1\ \mu$ thick, endospore wall $2.3\ \mu$ thick; companion cell lacking.

Parasitic in *Aphanomyces cladogamous* Dreschler.

Characteristic of *Olpidiopsis Aphanomyces* and *O. luxurians* (Shanor, 1939), as well, is the unilateral character of the swelling caused by these two parasites (fig. 10, 25, and 26). The resting bodies are formed in great abundance but require a greater length of time for maturation than those of *Pseudolpidium gracile*.

Olpidiopsis curvispinosa n. sp. and *Olpidiopsis brevispinosa* n. sp.—Up to the present time no other species of *Olpidiopsis* than *O. gracile* and *O. Pythii* have been described as occurring on *Pythium*. Isolation from soil collections was made of two species of *Pythium*, each of which was parasitized by a species of *Olpidiopsis*. The first species of *Olpidiopsis* forms resting bodies with long curved spines with a companion cell that may or may not be spiny (fig. 1 and 21) and is named *O. curvispinosa*. The second species has large, brownish resting bodies with fine short spines and a usually smooth companion cell (fig. 2 and 22) and is called *O. brevispinosa*.

OLPIDIOPSIS curvispinosa sp. nov.²

Zoosporangii globosis vel ovalibus, 12–68 μ diametro, pariete levi vel cum spinis brevibus. Zoosporis biflagellatis. Spora perdurante globosa vel ovali, 17–24 μ diametro, cellula adhaerente praedita. Episporio cum spinis curvatus usque ad 5 μ longis. Cellula adhaerente 14–20 μ diametro, levi vel cum spinis brevibus.

OLPIDIOPSIS curvispinosa n. sp.

Zoosporangia one to many in terminal or intercalary swellings of the host hyphae, spherical to oval in shape, 12 to 68 μ in longest diameter, cellulose wall smooth or with short bristles, one to three exit tubes. Zoospores with numerous small oil globules, elongate and somewhat reniform, biflagellate, flagellae of about equal length, attached near anterior end of spore. Resting spores, consistently with a companion cell, spherical to oval, 17 to 24 μ in longest diameter, containing one large oil globule surrounded by vacuolate protoplasm. Exospore wall with curved spines up to 5 μ in length. Companion cell spherical or oval, 14 to 20 μ , smooth or with short, closely set spines.

Collected on *Pythium* sp. from Chapel Hill, North Carolina, October, 1940.

OLPIDIOPSIS brevispinosa sp. nov.²

Zoosporangii 10.68–68.40 μ diametro. Zoosporis biflagellatis. Spora perdurante valde brunnea, globosa vel ovali, 10.68–45.10 μ diametro, cellula adhaerente praedita. Episporio cum spinis usque ad 3.56 μ longis. Cellula adhaerente 7.12–25.5 μ diametro, levi vel pariete spinoso.

Olpidiopsis brevispinosa n. sp.

Zoosporangia one to many in terminal or intercalary swellings of the host hyphae, swellings up to 125 μ in diameter. Zoosporangia 10.68 to 68.40 μ in longest diameter, wall smooth or with short bristles, with one to three exit tubes. Zoospores with numerous oil globules, elongate and somewhat reniform, biflagellate, the flagellae of about equal length, attached near anterior end of the spore. Resting spore consistently with a companion cell, dark brown, spherical to oval, 10.68 to 45.1 μ in longest diameter, spines on exospore wall up to 3.56 μ in length, endospore wall 0.75 to 1.32 μ thick, exospore wall 1.78 to 2.50 μ thick.

Collected December 27, 1941, by Philip Couch from Delhi, Louisiana. Parasitic on *Pythium* sp.

The zoosporangia of both of these species of *Olpidiopsis* are entirely similar so that morphologically the two species can be distinguished only by the differences in ornamentation of the resting bodies. Consistently the spines of the resting body of *O. curvispinosa* are bent with a characteristic flexuous appearance. There are, of course, variations in the length and degree of curvature of the spines but the general effect is quite different from that of the rest-

ing body of *O. brevispinosa*. The spines of the resting body of *O. brevispinosa* likewise vary in length but the average length is never as great as that of the spines in *O. curvispinosa*, nor do the spines curve and intertwine as in *O. curvispinosa*. The maximal size of the resting body of *O. brevispinosa* is almost twice that of *O. curvispinosa* and associated with this difference in size is a higher frequency of resting body formation in *O. brevispinosa*.

McLarty (1941) states that the character of the exospore is not a suitable, fundamental diagnostic character, though it is chiefly on the basis of exospore variations and host range that the species of *Olpidiopsis* have been determined. If, however, differences in exospore characters are accompanied by the limitation of the species in question to different host species, as is true of *O. curvispinosa* and *O. brevispinosa*, the species may be considered as valid until there is found a better means of species differentiation.

It was not possible to identify the species of *Pythium* which were attacked by *O. curvispinosa* and *O. brevispinosa*. The host of *O. curvispinosa* does not form oogonia in culture and the only reproductive structure is a filamentous zoosporangium (fig. 6). The vegetative hyphae vary in diameter from 3.2 to 4.3 μ . The host of *O. brevispinosa* also has filamentous zoosporangia (fig. 14) but in addition this species of *Pythium* produces oogonia (fig. 12 and 13) very readily. The oospores, 15.0 to 17.5 μ in diameter, do not fill the oogonium, which measures 20.0 to 25.5 μ in diameter. The antheridia are declinuous and may number one or more on an oogonium. The oogonia and zoosporangia appear to be quite similar to those of *Pythium gracile* but this *Pythium* form did not parasitize *Spirogyra* when placed in contact with filaments of *Spirogyra*.

HOST RANGE STUDIES.—Shanor (1940) has made observations on the host range of five species of *Olpidiopsis*, one of the species being *O. luxurians*. Similar, but less extensive, studies were made with the four species of *Olpidiopsis* discussed in this paper. The purpose of these studies was to obtain further proof of the distinctness of the four morphologically different species, assuming that the inability to transfer one species of *Olpidiopsis* to the normal host of another species of *Olpidiopsis* is an indication of physiological differences of value in diagnosing the parasite species.

Whether or not a given species of *Olpidiopsis* was able to parasitize a certain species of water mold was determined by the following procedure. A large number of spores of the parasite species were added to a hemp seed culture of the water mold to be tested. The cultures were examined for evidences of parasitism twenty-four and forty-eight hours after inoculation, at which time the young parasite was visible in the swellings of the host if infection of the host had been successful. This procedure in each case was repeated three times with consistent results. The results of these experiments are shown in table 1.

² The Latin descriptions were prepared by Alma Holland Beers.

TABLE 1. Chart of reactions of nine species of water molds to one or more species of *Olpidiopsis*. Infection is indicated by a plus sign while non-susceptibility is recorded with a zero mark. Dots opposite certain of the species of water molds in the columns under the names of the parasite species indicate that tests for parasitism were not made in these instances.

Host species	Parasite species			
	<i>O. curvispinosa</i>	<i>O. brevispinosa</i>	<i>O. gracile</i>	<i>O. Aphanomyces</i>
<i>Pythium torulosum</i>	+	0
<i>P. pulchrum</i>	0	0
<i>P. proliferum</i>	0	0
<i>P. sp.</i> (host of <i>O. curvispinosa</i>)	Host	0	0
<i>P. sp.</i> (host of <i>O. brevispinosa</i>)	0	Host	0
<i>P. rostratum</i>	0	0	Host
<i>Aphanomyces cladogamous</i>	Host
<i>A. laevis</i>	0
<i>Plectospora myriandra</i>	0	+

Olpidiopsis curvispinosa was the only parasite which infected a species of *Pythium* (*P. torulosum*) other than its normal host. *Olpidiopsis brevispinosa* did not infect either the host of *O. curvispinosa* or *O. gracile*. Likewise, of all the species of *Pythium* tested with *Olpidiopsis gracile* only its host species, *P. rostratum*, was susceptible. The results obtained with *Olpidiopsis Aphanomyces* were very interesting. The form of *Aphanomyces laevis*, which is the host of the *Olpidiopsis luxurians* studied by Shanor in this laboratory, was found to be unsusceptible to *O. Aphanomyces*. The infection of *Plectospora myriandra*, a water mold which looks like *Pythium* but discharges its spores as in *Aphanomyces*, might indicate a closer relationship of *Plectospora* to *Aphanomyces* than to *Pythium*.

SUMMARY

Pseudolpidium gracile on *Pythium rostratum* was studied, and Butler's observation that the resting body lacks a companion cell is confirmed. A species of *Olpidiopsis*, the resting body of which is without a companion cell was found on *Aphanomyces cladogamous* and is reported as *Olpidiopsis Aphanomyces* Cornu. Two new species of *Olpidiopsis*, *O. curvispinosa* and *O. brevispinosa*, parasitic on two different species of *Pythium*, are described. It was found that it was impossible to transfer any species of *Olpidiopsis* from the host species on which it was collected to the host of any other of the four species.

TOTAL AUXIN EXTRACTION FROM WHEAT¹

G. S. Avery, Jr., J. Berger and B. Shalucha

A PREVIOUS report from this laboratory (Avery, Berger and Shalucha, 1941) described in some detail the conditions affecting the maximum amount of auxin extractable from maize endosperm. Since wheat, like maize, gave much higher auxin yields when alkaline aqueous extracts were autoclaved a few minutes, it appeared that wheat contained an auxin precursor similar to the one reported for maize. The auxin made available by hydrolysis of the precursor in maize endosperm was reported to be relatively stable to heating with strong alkali (Avery, Berger and Shalucha, 1940) but unstable to heating with strong acid, thus suggesting indoleacetic acid.

Contrary to certain of these findings, high temperature aqueous extraction of auxin from wheat has been reported to give yields inferior to those obtained in low temperature extraction, losses occurring above 60°C. (Haagen-Smit, Leech and Bergren, 1941).² Yields were also reported to be decreased markedly when suspensions were heated at pH values higher than 10.5.

In the light of the foregoing we were led to examine the conditions affecting maximum auxin yields from wheat, particularly those involving temperature, time, and pH. Wheats of high and low protein content were included in the study to determine the effect of this variable on auxin yields, so that conclusions might be generalized as much as possible.

MATERIALS AND METHODS.—All auxin tests here reported are on wheats obtained from the United States Department of Agriculture, through the courtesy of Dr. M. A. McCall. The wheat samples are listed in table 1.

An American strain of Victory Oats grown by Marshall C. Rumsey, Batavia, New York, was used

¹ Received for publication May 14, 1942.

² While this article was in press, another paper appeared concerning auxin extraction from wheat (Haagen-Smit, *et al.*, Amer. Jour. Bot. 29: 500-506, 1942). The conclusions are essentially the same as those in the 1941 paper by the same authors. In view of the similarity in yields obtained by their 48-hour extraction method, and the 15-minute high temperature hydrolysis procedure reported in this paper, it would seem that the latter is to be preferred. The latter method has the advantage of making possible immediate assays, and is not as dependent upon a critical extraction time, *i.e.*, they report increasing yields up to 48 hours, and a marked decrease thereafter.

for all *Avena* tests, and the deseeded test method (Skoog), used for a number of years in this laboratory (Avery, Creighton and Hock, 1939), was employed for all auxin assays. At least two dozen test plants were used per assay, thus making possible calculations of yields which were in every instance from curvatures shown to be in the proportionality range, and close to 10°. After treatments involving pH control or autoclaving with strong alkali, suspensions of the ground wheat kernels were readjusted to approximately pH 6 before centrifuging, dilution and *Avena* assay. Auxin yields are expressed in total degrees *Avena* curvature (TDC), 100,000 TDC equalling *ca.* 1 microgram (μ g.) of indoleacetic acid. Differences of 20 per cent or less on auxin yield data for any one sample are considered to be within the outside limits of experimental variation.

Wherever temperatures of 120°C. are indicated, they were obtained by autoclaving at fifteen lbs. pressure. Control of pH was accomplished by standard buffer preparations, and with a glass electrode. The pH values reported represent the pH of the wheat suspension at the end of the extraction period. However, suitable buffer mixtures were used in all cases to maintain the pH during extraction at the point desired. In some instances, especially the forty-five-hour periods, it was also necessary to add acid or alkali at intervals to help maintain the desired pH.

OBSERVATIONS.—*Effect of temperature.* The procedure of Haagen-Smit, Leech and Bergren was used as reported; in addition, three other procedures were employed involving variations in temperature and time. Following their directions, dry whole wheat grains were soaked for four hours in a sodium hydroxide solution at pH 10.5, then ground in a glass mortar with carefully washed sand, and allowed to stand at 22°C. for forty-five hours (with 1 cc. toluene) with pH maintained at 10.5. The mixture was then centrifuged and the supernatant liquid assayed by the *Avena* test. Table 2 gives the results obtained from such experiments with a high and a low protein wheat.

It is clear from table 2 that there is no appreciable difference in auxin yields between long-period low-temperature and short or long high-temperature extractions, nor was the yield affected by soaking

TABLE 2. *Effect of temperature of extraction on auxin yield from wheat. The values given in this and subsequent tables are the averages of two or more assays, each of which was carried out with two dozen Avena test plants; all curvatures used in calculations of yields were in the proportionality range.*

Sample tested	pH during extraction	Auxin yield in 100 thousands of TDC (or micrograms indoleacetic acid) per gram air-dry seeds			
		22°C.		120°C.	
		15 min. ^a	45 hrs. ^b	15 min. ^a	45 hrs. ^a
1	10.5	1.1 ^c	1.9	1.8	2.2
3	10.5	0.7	2.9	3.2	2.6

^a Weighed samples of ground wheat kernels were suspended in M/10 borate buffer, pH 10.5, and treated as indicated. When necessary, pH was maintained at 10.5 by additions of 1.0 N NaOH. Suspensions were neutralized, centrifuged and assayed as usual.

^b These extractions were carried out according to the method of Haagen-Smit, *et al.*; see text.

^c The following is a sample calculation: with an average *Avena* curvature of 11.0° at a dilution of 1 gm. ground wheat in 100 cc. of 1.5 per cent agar-mixture, the yield, substituting in the formula, TDC/gm. =

$$\frac{\text{degrees curvature} \times \text{dilution} \times 100}{\text{weight in gms. of sample}}, \text{ is}$$

$$\frac{11 \times 100 \times 100}{1} = 110,000 \text{ TDC.}$$

Since 100,000 TDC = ca. 1.0 µg. indoleacetic acid, the yield is equivalent to 1.1 µg. of the latter.

whole grains before grinding. For the remaining experiments, therefore, batches of each of the wheat samples were ground finely and used as a uniform source of material.

Effect of time of hydrolysis.—The object of this experiment was to determine the auxin yields from wheats of different protein content, as influenced by heating at 120°C. and pH 9.3 for fifteen and sixty minutes. The data in table 3 indicate that auxin yield is unrelated to protein content of wheat. Moreover, extracts of wheats made at high temperatures show little or no differences in yield whether heated for fifteen or sixty minutes, thus giving further support

TABLE 3. *Effect of time of hydrolysis on auxin yields from wheats of varying protein content. Temperature 120°C., pH 9.3.*

to evidence presented in table 1, namely, that there is no significant loss of auxin at higher temperatures.

Effect of pH of extraction.—For this study low temperature forty-five-hour extraction was employed so that the results might be compared with those in the literature. The results are given in table 4. The data show very low yields at acid pH values,

^a Because of their glutinous nature, more concentrated extracts cannot be tested readily, hence the yields are as low or lower than indicated.

but these increase to a maximum at pH 10.5. At pH 11.5 the yields are only about 0.3 to 0.8 times those at pH 10.5, but are two to six times as high as at pH 7. These results differ from those of Haagen-Smit, *et al.*, in that their yield at pH 7 was 1.5 times as great as at pH 11.5. In general then, while the results obtained differ quantitatively in several details from those of Haagen-Smit, *et al.*, they agree in two main principles; namely, that mild hydrolysis with alkali increases the auxin yield, and that high alkalinity causes destruction.

The increases and decreases in auxin yield upon extraction at different pHs, appear unrelated to protein content of the samples assayed.

In maize auxin extractions (Avery, Berger and Shalucha, 1941) the drop in yield between pH 10.5 and 11.5 approximates only 15 per cent. However, the auxin in wheat, from the data in table 4, appeared to be more labile in the presence of alkali, and this lability was studied further.

Instability of wheat auxin in the presence of alkali.—It may be seen from table 5 that the yields on autoclaving with 0.1 N NaOH are appreciably smaller than the maxima obtained at pH 10.5 (table 4), while with 1 N NaOH the yields are not more than 15 to 37 per cent of the maxima. The one exception is sample no. 3, in which the yield is about 70 per cent of the maximum.

The destruction of wheat auxin upon treatment with alkali is in sharp contrast to the alkali-stability of pure indoleacetic acid, and the largest portion of the auxin from maize endosperm; 82 per cent of the latter was stable to autoclaving in 2.5 N NaOH for fifteen minutes. Separate tests have shown that pure indoleacetic acid autoclaved fifteen minutes in 1 N NaOH, in the presence of wheat, is completely

TABLE 5. *Effect of 0.1 N and 1.0 N alkali on auxin yield from wheat. Temperature 120°C., time fifteen minutes.*

^a Because of their glutinous nature, more concentrated extracts cannot be tested readily, hence the yields are as low as or lower than indicated.

stable thus indicating the absence of destructive catalysts.

The data on alkali-instability of auxin from five of the six wheats (tables 4 and 5) suggest that in these samples, an auxin other than indoleacetic acid accounts for 70 per cent or more of the total auxin present. There is no evidence of correlation between the amounts of alkali-stable or alkali-labile auxin and protein content.

Evidence for the existence of two auxin precursors.—To demonstrate the existence of at least one water-soluble precursor, the following experiment was done. A 0.5 gm. portion of wheat sample no. 3 was suspended in 10 cc. of water at pH 5.9 for fifteen minutes, at 22°C. The suspension was then clarified by both centrifuging and filtering. One aliquot of this clarified extract was assayed for auxin without further treatment. A second aliquot was autoclaved for fifteen minutes with an equal volume of M/10 borate buffer, pH 9.6. The auxin content of the unheated extract was found to be 17,000 TDC per gram, while the heated extract gave 94,000. These data are the average of four closely agreeing experiments. This increase of over five-fold demon-

strates the existence of a water-soluble precursor which is converted into auxin upon heating at an alkaline pH. However, it is apparent that not all the auxin precursor of this wheat is readily soluble, since a total yield of 300,000 TDC per gram (vs. 94,000) could be obtained from *suspensions* autoclaved at an alkaline pH.

Some of the data already presented, upon closer analysis, point to the conclusion that at least two precursors exist in certain of the wheat samples. One of these is a precursor of an alkali-stable auxin (possibly indoleacetic acid), the other, a precursor of an alkali-labile auxin. In table 6, figures are given for the minimal amounts of these precursors, calculated from three sets of experimental data.

The yields at pH 10.5 (table 4) represent the total auxin (free auxin plus auxin precursor) obtainable; they agree well with the total auxin yields obtained by autoclaving at pH 9.3, except in the case of sample no. 3.

We may assume that the yields after autoclaving in 1.0 N NaOH (tables 5 and 6) represent alkali-stable auxin, since in at least two cases (samples 3 and 5) yields do not decrease with increasing alkalinity. This auxin may be indoleacetic acid, since the latter is completely stable to such alkali treatment, whether in the presence or absence of wheat. The stability of indoleacetic acid to alkali treatment in the presence of this plant tissue confirms previous experiments on stability of indoleacetic acid to alkali upon autoclaving in the presence of corn meal (Avery, Berger and Shalucha, 1941).

The yields at pH 7 (table 4) may be considered the maximal amounts of free auxin. Separate extractions of wheat samples with ethanol or purified ethyl ether give lower yields of free auxin.³

³ Ethanol, twenty-four-hour extraction, gave 3.6 and 6.0 thousand TDC per gram for samples 1 and 3 respectively; ether, twenty-four-hour extraction, gave 6.0 and 8.6 thousand TDC per gram for samples 1 and 3. These extractions were all made with three changes of solvent in the twenty-four-hour period.

TABLE 6. *Evidence for the occurrence of precursors of two different auxins.*

Precursor of alkali-labile auxin.....	0.7	0.7	0.3	1.4	0.4	0.47

As an example of the calculations, let us consider sample no. 3. This wheat contains 2.0 μ g. indoleacetic acid equivalents of an alkali-stable auxin, and at most, 0.6 μ g. of this are present in a free form before hydrolysis with alkali, i.e., at least 1.4 μ g. of a precursor were hydrolyzed to produce an alkali-stable auxin. Of the 2.9 μ g. of total auxin obtainable, 0.9 μ g. was destroyed by 1.0 N NaOH. At most, 0.6 μ g. of free auxin was alkali-sensitive; therefore, at least 0.3 μ g. of a precursor was present which on mild hydrolysis with alkali produced an alkali-sensitive auxin. It is obvious, therefore, that two auxins differing markedly in their alkali-stability are formed upon mild hydrolysis with alkali. That these two auxins are derived from different precursors is a logical conclusion.

Preliminary work on the chemical nature of the free auxin in wheat no. 3 indicates that some of it is indoleacetic acid or an indole derivative. A purified fraction obtained from 4 kg. of wheat gave the Winkler color test for indoleacetic acid, with an intensity approximately proportional to the concentration of acid calculated to be present from the *Avena* assay of the same fraction (1.2 per cent pure indoleacetic on dry weight basis).

While the above results are considered to be clearly indicative of the presence of two precursors, it is understood that the evidence does not constitute conclusive proof.

Additional evidence for the existence of two different auxin precursors in higher plants already exists in the literature. It has been suggested (Went and Thimann, 1937, p. 65) that the increased auxin yields obtained on saponification of maize oil were due to hydrolysis of an ester type of auxin a precursor. It has also been shown that in maize endosperm 90 per cent of the total auxin obtainable is present as a precursor of indoleacetic acid (Avery, Berger and Shalucha, 1941). The maize kernel, therefore, as well as the wheat kernel, apparently contains at least two different auxins, as well as two different precursors.

DISCUSSION.—The highest yields obtained in this study are approximately half those reported by Haagen-Smit, *et al.* This dissimilarity in yield might be explained in part by differences in wheat samples used; also in part by differences in details of the technique of assay.

Indoleacetic acid was shown by Haagen-Smit, *et al.* (1941), to be present in maize, but no evidence was presented as to the chemical nature of auxin in wheat. Since we have found marked differences in the alkali-stability of the auxins from maize and wheat, we are studying the chemical nature of wheat auxin. Kögl, *et al.*, distinguished stability in the presence of alkali as a characteristic of indoleacetic acid, and reported the isolation of this compound from yeast, human urine, etc. (cf. Boysen Jensen, Avery and Burkholder, 1936). Since 1934 there have been few advances in the chemical identification of auxins extracted from plant material, but there has been a gratifying increase in the number of studies

reporting at least presumptive evidence for the presence of indoleacetic acid in higher plants: Lefèvre (1938), using color tests, etc., reported that radish, cauliflower, water cress and asparagus contained indoleacetic acid and related acids. Riker (1939) reported that "growth substances similar to beta-indole-acetic acid in their reaction to hot acid and alkali have been obtained by ether extraction from" . . . normal and pathological tomato tissue. Van Overbeek (1940) tested extracts of the brown alga *Macrocystis*, and found that "invariably the auxin present in it was destroyed by acid, but not by alkali, indicating that indoleacetic acid was present"; evidence from determinations of the diffusion coefficient supported this conclusion. Link, *et al.* (1940), studying the auxin content of certain aphids, and the host plants on which they lived, found both acid- and alkali-stable auxins. Avery, Berger and Shalucha (1940, 1941) presented strong evidence that 90 per cent of the total auxin in maize endosperm was probably indoleacetic acid, and this conclusion was independently confirmed by Haagen-Smit, *et al.*, who isolated indoleacetic acid from maize. The question now pressing for solution is the chemical nature of the approximately 70 per cent or more of the total wheat auxin which is not indoleacetic acid.

It remains to be demonstrated whether either of the auxin precursors in wheat is identical with that previously established for maize.

SUMMARY AND CONCLUSIONS

Total auxin yields from high and low protein wheats are of approximately the same magnitude whether samples are extracted for forty-five hours at 22°C., or for fifteen minutes at 120°C., i.e., a higher temperature during the extraction period greatly decreases the time required without decreasing the yield.

The highest yields are obtained when extractions are carried out at pH 9.3 to 10.5. Lower yields are obtained at pH 4, 7 and 11.5, but the yield at 11.5 is greater than at pH 7. Marked destruction of the auxin from five out of six wheat samples tested occurs upon fifteen-minute autoclaving with 1.0 N NaOH, in contrast to the alkali-stable auxin present in maize endosperm; thus 70 per cent or more of the total auxin is a compound other than indoleacetic acid.

Auxin yields are apparently unrelated to protein content.

Auxin yields from wheat samples of different protein content differ in magnitude as much as four-fold.

The probable presence is established of two precursors which are converted into two auxins upon hydrolysis at pH 10.5. These auxins differ markedly in their stability in the presence of alkali.

A NEW CHYTRID WITH GIANT ZOOSPORES: SEPTOCHYTRIUM MACROSPORUM SP. NOV.¹

John S. Karling

IN CONTINUATION of a survey begun in 1940 of the chytrid flora of the eastern United States the author made further extensive collections of water samples containing vegetable debris during a tour of the south and southwest in the late summer of 1941. Samples of water from roadside ditches, ponds, lakes, swamps, and flowing streams were collected in pint-size thermos bottles and baited with bleached fragments of young corn leaves, cellophane, and bits of Kleenex cleansing tissue. Pieces of ice were added to the bottles from time to time so that the samples were kept at temperatures varying from 38° to 45°F. By such means it was possible to prevent too rapid development of the fungi present during transportation from one locality to another and until time and better facilities were available for microscopic study. The samples of water thus collected and preserved were eventually brought to Columbia University, re-baited, and studied in the manner described by the author in previous publications (1941).

In collections from Arkansas an unusually large chytrid occurred which appears to be new. It was first found in a water sample taken from a roadside ditch near Forest City, Arkansas, which had been baited with Kleenex cleansing tissue. By the time this sample reached New York City the rhizomycelium of the fungus had completely ramified the tissue and formed a dense network of hyphae, rhizoids, and zoosporangia among the cellulose fibers. The same species was next collected in a cyprus swamp near Little Rock, Arkansas, and since that time it has also been found in Texas, Louisiana, Mississippi, Alabama, Florida, Georgia, South and North Carolina, Virginia, and Tennessee. It has also been collected recently near Greenwood Lake, New Jersey, which indicates that it has a very wide distribution.

This species is characterized by an unusually coarse rhizomycelium, operculate zoosporangia, and

giant zoospores. Apart from the absence of pseudo-septa or trabeculae in the tenuous portions of the rhizomycelium, its structure, development, and organization are fundamentally the same as those of the genus *Septochytrium*. It is accordingly included in this genus for the time being and named *S. macrosporum* sp. nov. because of its unusually large zoospores.

SEPTOCHYTRIUM macrosporum sp. nov.—Fungus saprophyticus; thallo praecipue polycentrico, rhizomycelio, 5-15 μ dia.; zoosporangiis hyalinis, laevis, globosis, 15-280 μ , pyriformibus, 30-50 \times 70-190 μ , fusiformibus, irregularibus; operculatis 9-16 μ dia. Zoosporis hyalinis, globosis, 11-13 μ dia. Sporis perdurantibus laevis, verruciformibus, luteo-brunneis, globosis, 25-115 μ , ovatis, 30-50 \times 40-75 μ .

Septochytrium macrosporum sp. nov.—Thallus predominantly polycentric, occasionally monocentric. Rhizomycelium unusually coarse, richly branched, rarely septate, with thick walls which stain brick-red to reddish-lavender with chloro-iodide of zinc; tenuous portions apart from rhizoids 5 to 15 μ in diam.; rhizoids numerous and richly branched; intercalary enlargements broadly or narrowly spindle-shaped, elongate, fusiform, and irregular. Zoosporangia terminal or intercalary, delimited from remainder of thallus by cross septa, non-apophysate, spherical, 15-280 μ , pyriform, 30-50 μ \times 70-190 μ , obpyriform, broadly fusiform, obclavate, utriform, and sometimes irregular; hyaline and smooth; opercula 9-16 μ in diam. Zoospores spherical, 11-13 μ , average 12.2 μ , with one larger, 2.5-3.5 μ , and three to six minute refractive globules; emerging fully formed and lying quiescent for a few moments in a globular mass at the exit orifice before swimming away; intermittently amoeboid. Resting spores intercalary, oval, 30-50 \times 50-75 μ , spherical, 25-115 μ , amber, and yellow to light-brown in color, smooth or covered with coarse, simple or branched

pegs or filamentous extensions, 4–18 μ long; wall 4–6 μ thick, content coarsely granular with one to several large refractive granules; germination unknown.

Saprophytic in vegetable debris in ponds, brooks, lakes, swamps, etc., in Arkansas, Texas, Louisiana, Mississippi, Alabama, Florida, Georgia, Tennessee, South and North Carolina, Virginia, and New Jersey, U. S. A.

In diameter of rhizomycelium and extent of growth as well as zoospore size, *S. macrosporum* is the largest of all known polycentric chytrids. Apart from the spindle-shaped intercalary swellings which are usually quite large, the tenuous portions of the rhizomycelium may, in exceptional cases, attain a diameter of 15 μ (fig. 1F), and on cellophane single thalli have been found to extend over a distance of 3.5 mm. In addition, the zoosporangia may sometimes be almost 300 μ in diameter. While such large thalli are exceptional, they nevertheless indicate the remarkable size which this species may attain. Figure 1, except the resting spores, is a drawing of a portion of the rhizomycelium in a piece of cleansing tissue from the original material collected at Forest City, Arkansas, and illustrates quite well the extent of branching and richness of thallus development. In cellophane and corn leaves, however, the frequency of branching may be considerably less, so that long tubular unbranched filaments up to 200 μ in length may sometimes be found (fig. 11). However, as the rhizomycelium grows out from pieces of cellophane into the water, its habit of growth changes markedly. It becomes loosely or closely coiled as is shown in figure 12 and rarely follows a straight line. Growth on corn meal and potato dextrose agar is rather slow, but the rhizomycelium branches more frequently than in cellophane. In all types of media and substrata, branching usually occurs most abundantly in the vicinity of the intercalary enlargements, as is shown in figures 1 and 11. Rhizoids are usually abundant and may arise from the surface of sporangia and intercalary enlargements (fig. 1, 11) as well as from the tenuous portions of the rhizomycelium. Well-defined cross walls delimit the zoosporangia and resting spores, but no septa have been found in other parts of the thallus. No constrictions in the filaments nor bands nor trabeculae of opaque material which extend partly or completely across filaments have been observed in this species. The lack of these characters distinguishes the rhizomycelium of *S. macrosporum* sharply from that of the type species, *S. variabile*, described by Miss Berdan (1939, 1941). As noted elsewhere, the walls of young thalli stain brick-red or reddish-lavender when tested with chloro-iodide of zinc. In large old thalli the walls usually become thick (0.7–1.8 μ) and rigid, and withstand disintegration for several months.

While the thallus of *S. macrosporum* is predominantly polycentric, it may often be monocentric in

small reduced thalli (fig. 13). In such instances, it is strikingly similar to the thallus of *Endochytrium operculatum* and may be easily mistaken for the latter species. Such thalli may be monorhizoidal with the main axis of the absorbing system attached at the base or polyrhizoidal with numerous rhizoids arising from the lower periphery of the sporangia. In these thalli the single sporangium originates from the initial intramatrical swelling on the germ tube.

The zoospores of *S. macrosporum* emerge singly and fully developed from the sporangia and lie inactive for a short while at the exit orifice before swimming away. As a result, a large globular mass of spores accumulates at the apex of the sporangium as is shown in figure 1A. However, this mass usually breaks up before most of the zoospores have emerged, so that a large number of spores are generally to be found in the sporangia. These soon begin swarming within, and as the individual spores reach the exit orifice they emerge (fig. 1D) and swim directly away without coming to rest. In cover glass mounts the exit orifice may sometimes become closed by pressure or obstruction, and in such cases the trapped zoospores may continue to swarm for many hours before coming to rest within the sporangium. In one case of a sporangium with eight trapped zoospores active motility continued for forty-two hours. Such zoospores eventually become inactive, and it is not uncommon to find sporangia with numerous quiescent zoospores like those shown in figures 1B to 1E.

The zoospores of *S. macrosporum* are larger than those of any known chytrid and also most species of the Blastocladales, Monoblephoridiales, Saprolegniales, and Peronosporales. They nevertheless have the typical chytridiaceous appearance, structure, and type of motility (fig. 2–5). The refractive globule seems quite small in proportion to the size of the spore body, although it ranges from 2.5 to 3.5 μ in diameter. In addition to this globule, the zoospore contains three to six minute ones which impart a slightly greyish granular appearance to the zoospore. Because of the relative minuteness of these refractive globules, the mature zoosporangium with fully delimited spores appears less refractive and more greyish granular than those of *S. variabile*. In fixed and stained preparations, the nucleus of the zoospore, in median longitudinal views, is obpyriform and tapers toward the point of attachment of the flagellum (fig. 2). Enveloping its upper one-third is a densely-stainable lunate body or nuclear cap, of the type described by the author (1937) in *Cladochytrium replicatum*. This body may also become faintly visible in living zoospores toward the close of their motile or amoeboid stage (fig. 4). When observed from the posterior end of the zoospore, the nucleus in living spores often appears to lie in a vacuole as is shown in figure 3. Occasional bi- and triflagellate zoospores (fig. 6, 7) have been

Coiled rhizomycelium growing in water at the edge of a piece of cellophane.—Fig. 13. Monocentric reduced thallus.—Fig. 14. Smooth resting spore in median view.—Fig. 15. Median view of resting spore with warts and branched pegs on its surface.

found, which appear to be the result of incomplete or unequal cleavage. Some of the biflagellate individuals have been seen to constrict and undergo fission (fig. 6). Triflagellate zoospores with a diameter of $18\ \mu$ have occasionally been found.

Germination of the zoospores and the development of the thallus in *S. macrosporum* are fundamentally similar to those of other cladocytriaceous chytrids with intercalary enlargements in the rhizomycelium and need not be described in detail. As is shown in figures 8 to 10, one and sometimes two or three thick germ tubes are formed which penetrate the substratum and begin to branch. A fusiform swelling may develop in the germ tube (fig. 10) before it branches or later. These swellings may remain comparatively small or develop into zoosporangia. In any event, they function as vegetative centers of growth, organization, and reproduction. They do not, however, become uni- or multiseptate as in *Cladocytrium replicatum*, *C. tenue*, etc. Although no intensive study of fixed and stained material has yet been made, it will probably be found that the nuclei are localized in these enlargements as has been shown for *C. replicatum*. The germ tube continues to grow and elongate until an extensive rhizomycelium with numerous rhizoids is established. The intercalary zoosporangia develop from the fusiform swellings, and in the early developmental stages it is impossible to determine whether a sporangium or merely an elongate swelling is to be formed. The terminal zoosporangia, on the other hand, develop by enlargement of the tips of the rhizomycelium.

The protoplasm of the developing rhizomycelium has a characteristic vacuolate and alveolar structure, as is shown in figure 1. The refractive material is often greatly dispersed, so that the protoplasm has a distinct greyish-granular appearance. This is true to some extent of the contents of the zoosporangia also, and as a result the interior of mature sporangia appears less refractive (fig. 1H, 12A) than that of *S. variable*, *Endochytrium operculatum*, etc.

Thick-walled dormant spores have been found only in the collections of material from Greenwood Lake, New Jersey. They were first observed by Miss A. Johansen in cultures kept for several days in a refrigerator at approximately 5° to 10°C ., and the writer is very grateful to her for these data. Whether or not the spores were formed in reaction to the low temperatures is uncertain, since additional experiments along this line have not been successful. So far, only intercalary resting spores have been found (fig. 11A-11E), and these develop in the same manner as the zoosporangia from intercalary swellings. Up to a certain stage the two are indistinguishable, but after that the protoplasm of the incipient resting spores becomes more coarsely granular and refringent. Simultaneous with these changes, the wall begins to thicken, and in mature spores it may attain a thickness of $6\ \mu$. In this respect *S. macrosporum* differs markedly from *S. variable*. The wall appears to consist of more than one layer and is usually yellow, amber, and light brown in color with a faint

tinge of green. In the smooth spores its outer periphery may often appear slightly incrustated (fig. 14) as if material from the substratum had condensed on its surface. The content of most spores is coarsely granular, and in only two instances so far have spores with one large refringent globule been found. In a few cases the spores only partially filled a thin-walled vesicle (fig. 1G, 11B, 14), which suggests that the contents of the incipient spores contracted and became invested with a thick wall, leaving the remainder of the original vesicle empty. That such structures are to be interpreted as rudimentary oogonia with a single oospore is quite unlikely, in the author's opinion.

As noted in the diagnosis above, two types of resting spore occur—smooth ones and others, the outer wall of which is covered with blunt pegs or short, coarse, hypha-like branches (fig. 11D, 11E, 15). Whether the latter are true resting spores or zoosporangia which have encysted and developed thick walls is not altogether certain at present, since all of their developmental stages have not been seen. However, a few incipient thin-walled stages have been found in which the sporangia-like vesicles were covered with numerous short rhizoids, which suggests that the branches shown in figure 15 are rhizoids that have thickened and become contorted. Figure 15 shows a median section of such a spore. Its coarsely granular content and thick wall are strikingly similar to those of the smooth spores. So far, germination of these resting spores has not been observed, but it doubtless occurs in the same manner as in *S. variable*.

In addition to *S. macrosporum*, described above, a large number of well-known chytrids were collected on this survey. The range of these species has thus been greatly extended. Inasmuch as no extensive collections of saprophytic chytrids have been made previously in many of the southern and southwestern states, the species collected on this survey are listed according to the states visited.

Nowakowskiella hemisphaerospora, *S. macrosporum*, and *S. variable*. Nashville, Tennessee, 1941.

TEXAS

In addition to the species reported previously (1941b) from Texas, *Nowakowskiella hemisphaerospora*, *Septochytrium macrosporum*, *S. variable*, and *Nephrochytrium aurantium* were collected at Hamilton Pool on the Pedernales River and at Barton Springs, Austin, Texas.

VIRGINIA

Septochytrium macrosporum and a large saprophytic *Diplophlyctis*-like species were collected in the swamps near the Pamunky River, New Kent County, January, 1942, in addition to the chytrids listed from this region in 1941. The *Diplophlyctis*-like species is considerably larger in sporangium and resting spore size than either *D. intestina* or *D. laevis* and may possibly be a new species. It is now under investigation at Columbia University.

This brief and incomplete survey of chytrids in the southern and two southwestern states shows that the large saprophytic species are well distributed, and as common in occurrence as other aquatic fungi. Particularly noteworthy is the wide distribution of species of *Cladochytrium*, *Endochytrium*, *Nowakowskiella*, and *Septochytrium*. *Diplophlyctis intestina* and *E. heliomorpha* were present wherever species of *Nitella* and *Chara* were collected. *Nowakowskiella ramosum*, which had hitherto been reported only once from the New World (Karling, 1941b), was found in two new localities, Alabama and Florida, while *N. hemisphaerospora* proved to be as widely distributed as *N. elegans* and *N. profusum*. *Nowakowskiella hemisphaerospora* was first collected by the writer in Virginia in 1938 and kept in culture since that time, but no opportunity was available to complete a study of its life cycle. It has recently been fully described and diagnosed as a new species by Shanor (1942), who found it in Illinois. The present survey indicates that it is very common in occurrence. The thalli of what was reported as *C. carolineanum* from Cyprus Garden, South Carolina, were nearly all elongate, cylindrical and tubular and strikingly similar to those of *Cylindrochytridium Johnstonii*, except for the lack of a septum and other differences in the compound apophysis. Whether this isolate is a new species, a strain, or variety of *C. carolineanum*, or merely represents variations of the latter species is now being determined from mono-zoospore cultures. Its similarity in shape, appearance and structure nevertheless suggest a close rela-

tionship between *Cylindrochytridium* and *Catenochytridium*.

In addition to *S. variable* and *S. macrosporum*, a third species of this genus was found in Alabama, North Carolina, and South Carolina. It differs chiefly from the other two species by the lack of a conspicuous refractive globule in the zoospores. Instead, they contain numerous minute granules which give the zoospores a characteristic greyish granular appearance. In addition, its rhizomycelium, apart from the sporangia, is wavy and undulating in contour. It lacks the septa or trabeculae of *S. variable* and in general is smaller than *S. macrosporum*. What appears to be the same chytrid has since been collected by Miss A. Johansen in New Jersey and is now under investigation. Resting spores of *Catenaria Anguillulae* were abundant in the material collected in Cyprus Gardens, South Carolina, and this is the first report of their occurrence in the New World. They are spherical, 20–35 μ , oval, 20–30 $\mu \times$ 40–50 μ , oblong, 30 \times 60 μ , full of yellowish-amber refractive material, and have a fairly thick hyaline

wall. As Buckley and Clapham (1929) have shown in England, they are sometimes formed by the contraction and encystment of the contents of incipient zoosporangia. It is, therefore, not uncommon to find resting spores lying in uteriform vesicles which have a long unopened exit tube.

SUMMARY

Septochytrium macrosporum n. sp. was first collected at Forest City, Arkansas, and has since been found in vegetable debris in Alabama, Florida, Georgia, Louisiana, Mississippi, New Jersey, North Carolina, South Carolina, Tennessee, Texas, and Virginia. It is the largest of all known chytrids and is characterized by an unusually coarse and extensive rhizomycelium, giant zoospores, and smooth and warty resting spores. The spherical zoospores range from 10 to 13 μ in diameter and are among the largest of all known aquatic fungi.

BREEDING WORK TOWARD THE DEVELOPMENT OF A TIMBER TYPE OF BLIGHT-RESISTANT CHESTNUT: REPORT FOR 1941¹

Arthur Harmount Graves

JAPANESE-AMERICAN HYBRIDS.—Our breeding work with the chestnut was started in 1930, with the aim of combining the tall, erect habit of the American tree with the disease resistance of the Japanese species, a tree of comparatively low stature. The ultimate purpose has been to develop a disease resistant chestnut tree of timber type for reforestation purposes, to replace the American chestnut tree, *Castanea dentata*, now practically extinct, at least as a forest tree.

From 1932 to date the germination of the hybrid nuts has been good, and since we have each year continued the breeding of these two species, using

¹ Received for publication May 16, 1942.

Brooklyn Botanic Garden Contributions, No. 97. Recent popular annual reports have been published in the Brooklyn Botanic Garden Record, as follows: for 1937, 27: 44–55; for 1938, 28: 52–60; for 1939, 29: 58–63; for 1940, 30: 87–92; for 1941, 31: 94–99.

We are pleased to acknowledge the continued cordial cooperation of the Division of Forest Pathology, U. S. D. A. Also to the many individuals and institutions that have sent us pollen or nuts, or have helped us in other ways, we take pleasure in expressing our appreciation.

many varieties of the Japanese parent, we now have a considerable number (about 150) of F₁ Japanese-American hybrids, ranging in age from one to ten years. Repeated tests by inoculation, by the method described by the writer (1938b), with the causal fungus in these F₁ hybrids show conclusively that they are susceptible to the blight; not, it is true, to such a degree as the American parent is, but sufficient to make them useless for reforestation stock, at least for tall timber trees. However, their erect habit is like that of the American parent; and in many individuals, the annual rate of growth far surpasses that of the American (Graves, 1938a).

THE GENETIC SITUATION.—We have now reached a point where we can sketch roughly the genetic situation in these Japanese-American hybrids with regard to their growth habit and resistance or susceptibility to the blight.

Let us represent the tall, erect growth of the American chestnut (*Castanea dentata*) by T, and its susceptibility to blight by S. Then the comparatively low stature of the Japanese species (*C. cre-*

nata) may be designated by t, and its disease resistance by s.

Accordingly, when *Castanea dentata*, TTSS, is crossed with *Castanea crenata*, ttss, each one of the offspring may be represented by TtSs, where tallness and disease susceptibility are dominant. This, it will be seen, corresponds essentially to the situation as we now find it among our F₁ Japanese-American hybrids.

That the case is, in all probability, not so simple as this, is obvious. For the "tallness" may be a combination of several factors; e.g., annual rate of growth, or, better, relative rapidity of growth, and also growth habit, i.e., direction of growth, the latter depending possibly on the relative quantity (or quality) of growth hormones in terminal and lateral buds, as determining whether the growth shall be orthotropous or plagiotropous. Also, "susceptibility" is, in all likelihood, not the result of a single factor, a partial evidence of which we have in the fact that the F₁ hybrids are more disease resistant than the American parents. Possible factors which combine to produce disease resistance may be the relative osmotic tension of cells, or of particular tissues (which may differ at different periods of the year), relative thickness of cell walls, character of cell contents—qualitative and quantitative—rapidity of formation of new tissues, etc. However, at present, any attempt to state the factors operating is largely a matter of speculation. The fact remains that in the F₁ Japanese-American hybrids the American characteristics are dominant.

FURTHER BREEDING OF THE F₁ JAPANESE-AMERICAN HYBRIDS.—If the case were a simple, bifactorial one, the further breeding of the F₁ hybrids would yield on the average for every sixteen of the progeny: nine tall and susceptible, three tall and resistant, three dwarf and susceptible, and one dwarf and resistant. But, as we said above, the case is obviously not as simple as this. Nevertheless, we know that the proportion of the desired offspring resulting from such further breeding will be greater or lesser, depending on the actual complexity of the genetic constitution. And, furthermore, it is evident that in order to obtain the desirable forms, the breeding must be continued beyond the F₁ stage, either by interbreeding the F₁s, or by backcrossing with disease resistant individuals.

This whole situation was foreseen, or rather suspected, in 1937, at which time we began interbreeding our hybrids, and also backcrossing them, not only with resistant Japanese but with resistant Chinese, with the result that we now have a considerable number of F₂s and a combination of F₁s and resistant Japanese or Chinese in both our own and cooperative plantations (Graves, 1940). Some of these flowered this year (see third starred item in table 1) and the breeding is being continued with them.

A SIMILAR CASE IN TOBACCO BREEDING.—The case of the Japanese-American chestnut hybridization has some points of similarity with the breeding of

certain tobaccos now under way at the Connecticut Agricultural Experiment Station. An account of that work has not yet been published, but I have the permission of Dr. P. J. Anderson of the Tobacco and Vegetable Substation at Windsor, Connecticut, to give a general outline of the work and indicate the results to date. Dr. Anderson (1918) is also well known for his work on the chestnut blight fungus, *Endothia parasitica* (Murr.) P. J. & H. W. Anderson.

The Connecticut Broadleaf tobacco, which has very broad leaves but is susceptible to the mosaic disease, is being bred with a tall, disease resistant

Fig. 1. Japanese-American hybrid chestnut (*Castanea crenata* × *C. dentata*, Hammond, 99A33) eight years old, showing three basal shoots inarched (in spring of 1941) in order to keep tree alive and vigorous for further breeding. Tree is blighted for more than half of circumference at base near ground. Photo by Louis Buhle, September 13, 1941. (Photograph loaned by Brooklyn Botanic Garden.)

variety known as Ambalema, imported from Colombia, South America. In the F_1 generation all plants were susceptible to the mosaic, but in the F_2 generation the expected segregation occurred in such a way as to indicate that disease resistance is a regular recessive character. By selection of desirable individuals and backcrossing, Dr. Anderson says, in correspondence, "I am getting much nearer to the qualification which I require, but have not yet obtained a seed which I am ready to distribute or recommend to the grower. This may take several more years of selection, but I feel sure that it is only a question of perseverance and patience, and the qualities can be definitely obtained." In our chestnut breeding work the progress will naturally be much slower than it is with tobacco where two generations can be obtained each year. In the Japanese-American hybrid chestnuts the generations are usually from three to six years apart.

Fig. 2. Japanese-American hybrid chestnut (*Castanea crenata* \times *C. dentata*, Minturn 14-33) showing four inarchings of basal shoots. Tree eight years old, badly blighted near base. Photo by Louis Buhle, September 13, 1941. (Photograph loaned by Brooklyn Botanic Garden.)

METHOD OF PROLONGING THE LIFE OF F_1 JAPANESE-AMERICANS FOR FURTHER BREEDING.—The fact that the F_1 Japanese-American chestnuts ordinarily contract the blight early in life (usually before the age of ten years) makes it difficult to continue breeding with them in order to bring about the segregation above indicated; for, if badly blighted, they become sickly and soon die, at least above ground. Especially is this true when the blight fungus attacks the tree at the base, as often happens. In this case, however, young shoots or "suckers" are usually developed from the root collar at the ground level. It is then a simple matter to graft the tips of these shoots into the trunk above the lesion caused by the blight. In 1941 several trees were rehabilitated in this way. Figure 1 shows a tree that was blighted for more than half of the circumference of the trunk at the base, but by the method above described, three basal shoots were turned into the trunk above, with the result that the tree was vigorous during 1941, was crossed with another F_1 , and bore a good crop of hybrid nuts. Figure 2 shows a tree in which, on account of a somewhat higher location of the lesions, the grafts were made much higher up.

CHINESE-AMERICAN HYBRIDS.—We began crossing the American and Chinese species in 1934, using for the Chinese parents fine specimens that had been given us in 1929 (then two years old) by the Division of Forest Pathology, U. S. D. A. Our inoculation experiments have shown that the Chinese species, *C. mollissima*, is the most blight resistant of all. Figure 3, from a photo taken in September, 1941, shows the size and growth habit of some of these trees, then fifteen years old, at our plantations at Hamden, Connecticut. The spreading habit is characteristic of the Chinese species, and the photograph shows how unsuited the tree is for forest planting. In closely planted stands, however, the individuals would probably be more erect. In 1935 we set out a large number of these trees, from nuts obtained from open pollination, to determine what will be their form in a close stand planted six feet apart. As a matter of fact, there seems to be considerable variation in this species as regards habit of growth. There are reports of fairly tall individuals with an excurrent growth habit. It would, of course, be desirable to use such stock for crossing: we should like to obtain scions of such stock.

Our Chinese-American hybrids, therefore, are still young, so that we are not yet prepared to make a preliminary statement about their genetic situation.

OTHER HYBRID FORMS.—Our past reports show a large number of crosses which do not seem to bear any definite relation to the problem in hand. These were made for various reasons, stated in the reports. If time permits, we shall try to develop them further. Most of them, however, relate to some quality of the nuts—fruitfulness, early ripening, size, flavor, number in a bur, or the everbearing character. However, the qualities of the nuts are economically of transitory importance as compared with the value of good chestnut timber.

Fig. 3. Row of Chinese chestnut (*Castanea mollissima*), fifteen years old, showing low-growing, deliquescent habit with thick, sturdy, lateral branches, often almost horizontal. Photo by Louis Buhle, September 13, 1941. (Photograph loaned by Brooklyn Botanic Garden.)

HYBRIDS OF 1941.—A total of 260 hybrid nuts was harvested in 1941. In line with what has been said above, 135 of these were obtained from backcrosses of Japanese-American hybrids, 50 came from interbreeding of Japanese-American hybrids, and 24 were the result of first crosses of the American chestnut (*C. dentata*) with our best Japanese trees. As usual (since 1934) all of the cross pollinating was done at our plantations at Hamden, Connecticut. We received pollen by mail from various sources, and a list of donors with our acknowledgment of their co-operation has been presented in the thirty-first Annual Report of the Brooklyn Botanic Garden (Graves, 1942).

In table 1 the female parent is given first. The combinations new to science are preceded by an asterisk.

VARIATION IN THE CHESTNUT.—In our last report we discussed the question of the occurrence of variation in the American chestnut, particularly along the line of ever increasing resistance to the parasitic fungus which induces the blight. The possibility of the occurrence of variation was based partly on the fact that at the present time vast numbers of young basal shoots are arising from stumps or the bases of diseased trunks all over the natural range of the American chestnut. This situation, as has been proved by the writer (1926), is due to the fact that the roots of chestnut resist the attacks of the fungus with much greater vigor than do the parts above ground. The condition has also been likened to a pruning operation in which the upper parts are cut off, the lower parts being thus forced to develop. The case of

^a *C* × *D* = *C. crenata* × *C. dentata*.

^b *S8*, one of the Van Fleet chestnut hybrids, is apparently a combination of *C. crenata* and *C. pumila*. The *S8*'s in our plantation are from open pollinated seedlings of *S8*.

Cytisus Adami has been cited, the upper part of a branch of which was cut off by Beyerinck (1900), the lower part, being thus forced to grow out, showing segregation and appearing in quite a different form. This example, as has been pointed out by one of our correspondents, was unfortunate, since in all probability, *Cytisus Adami* is a graft hybrid (Jones, 1934), although De Vries (1910) did not think so.

The fact remains, however, that a very large number of these basal shoots are being developed, and probably will continue to be developed for many

years to come, affording plenty of opportunity for natural variation. The possibility of variation in the direction of disease resistance should not be ignored. We are, therefore, planting all nuts of *Castanea dentata* sent us from many parts of the eastern states. Last fall we received them from seven states. If nuts are sent, they should be wrapped in moist cotton or sphagnum and should be mailed as soon as possible after they are gathered. We have learned that drying out kills the embryo. Address: A. H. Graves, Brooklyn Botanic Garden, 1000 Washington Avenue, Brooklyn, New York.

SUMMARY

In the F_1 Japanese-American hybrid chestnuts the American parent is incompletely dominant. In order to continue breeding for the desired result, namely a blight-resistant chestnut of tall erect

growth, suitable for a timber tree, the F_1 hybrids are being kept in vigorous condition by a kind of bridge grafting. No definite statement of the genetic situation in the Chinese-American hybrids can yet be made.

A situation in the breeding of certain types of tobacco which is similar in some respects to that of the Japanese-American hybrids of chestnut is briefly described.

A record of the results of breeding of various chestnut species and hybrids in 1941 is given, including four combinations new to science.

It is stated that the possibility of natural variation in the chestnut in the direction of disease resistance should not be ignored, and in this connection a plea is made for native nuts to be sent to the Brooklyn Botanic Garden.

A CYTOLOGICAL INVESTIGATION OF POLYGONATUM USING THE COLCHICINE-POLLEN TUBE TECHNIQUE¹

O. J. Eigsti

POLYGONATUM, the Solomon's Seal, is represented in many localities in eastern and central North America. In spite of this wide distribution, the abundance of cytological material which each plant affords, and the simplicity of study by the aceto-carmin technique, not much information is recorded concerning the cytology of the American

¹ Received for publication May 18, 1942.

Contribution from the Botanical Laboratory, University of Oklahoma, No. 74. This project was supported in part by a University Research Grant.

The author is grateful to Dr. G. L. Cross and Dr. Milton Hopkins of the Department of Botany for their valuable advice and helpful criticism offered during the progress of this work and the preparation of the manuscript. Mr. Elroy Rice and Mr. Tillman Johnson aided in the photomicrographic work. In addition to all those persons (table 2) who made possible these collections, the author gratefully acknowledges the information secured by letters from Dr. L. O. Gaiser; Dr. J. T. Baldwin, Jr.; the late Dr. Karl Wiegand; Dr. W. A. Anderson; Dr. Charles Deam; and Dr. Ruth P. Owenby.

species of this genus (Cardiff, 1906; Cartledge, 1933). More is known about the Asiatic and the European species (Matsuura and Sutô, 1935; Sutô, 1936; Hasegawa, 1933; Tischler, 1927, 1937, 1938). Although three taxonomic treatments have been published since 1915 (Farwell, 1915; Gates, 1917; Bush, 1927) which were intended to solve the taxonomic difficulties encountered in classifying the species by using the available manuals, the differentiation of those species having glabrous leaves is still difficult, and the proper identification of them is a vexing task. It is true that most taxonomic keys are unsatisfactory for the genus; however, recent treatments (Farwell, 1915; Gates, 1917; Bush, 1927) have not clarified the situation entirely. Deam (1940), Wiegand and Eames (1925) and undoubtedly others have found the definition of a species rather vague and the limits of the species indefinite. An objective of this study is to show how cytologi-

cal information has a bearing upon the taxonomic situation, since the problem of species relationships is closely related to the occurrence of tetraploidy among species of the genus.

Incidental to a study of the effects of colchicine upon mitotic activities of the pollen tube of *P. commutatum* (R. & S.) Dietr. (sensu Gray's Manual, 7th ed.) the present writer discovered that this species is a tetraploid ($2n=40$) (Eigsti, 1940a, 1940b). Additional collections of plants from other regions revealed that there are diploid plants ($2n=20$) very much like the tetraploid plants ($2n=40$) except for size (Eigsti, 1940d, 1941a). However, certain diploids with foliar pubescence (*P. pubescens* (Willd.) Pursh, $n=10$) are taxonomically different from either of the glabrous species, *P. biflorum* (Walt.) Ell. and *P. canaliculatum* (Willd.) Pursh. As early as 1917 Gates (1917) called *P. giganteum* Dietr. a mutant, but apparently no cytological verification of this assumption was published. Asa Gray recognized the *gigas* features of the tetraploid (Eigsti, 1941b) by naming the large species the "Great Solomon's Seal" and the smaller one the "Small Solomon's Seal," a distinction often correlated with polyploidy.

The method of securing cytological information by the use of pollen-tubes and the colchicine technique represents a new approach for cytotaxonomic investigations. A haploid complement of chromosomes in the generative cell is used for the basic morphological studies of the chromosomes. The chromosomes are scattered in the pollen tube and in such position are counted easily and measured with greater accuracy because of the straightness of the metaphasic chromosomes (Eigsti, 1940c). Also the region of the kinetochore can be located in a precise fashion, thereby facilitating comparative studies of the arms of the various chromosomes of the complement.

MATERIALS AND METHODS.—Because numerous requests have been received in regard to this pollen tube technique, more than the usual detail of procedure is given in the following ten steps.

(1) Flowers at the time of anthesis are brought to the laboratory for inoculations.

(2) A solution of sucrose and agar is prepared by dissolving 2 grams of agar and the proper amount of sucrose in 100 cc. distilled water (pH 6.5–7.0). The amount of agar used is twice the concentration required for germination because a dilution is made before the final spreading of the film over the slide. Likewise, the concentration of sucrose is twice that required for each particular type of pollen for reasons made clear in step (4).

(3) A 0.02 per cent aqueous solution of colchicine is prepared.

(4) Colchicine solution (3) is mixed with the sucrose-agar mixture (2) in equal proportions. To effect a proper mixture, calibrated vials are used.

(5) A vial (about 6 cc. capacity) containing sucrose-agar-colchicine is kept in a small, wide-

mouth bottle which serves as a water bath (temperature about $48^{\circ}\text{C}.$).

(6) A thin film of colchicine-sucrose-agar, sufficient to cover a glass slide, is made with a camel's hair brush (no. 3).

(7) Immediately after the film is spread pollen is introduced onto the medium by shaking the flower over the slide or by dipping the anther into the substrate.

(8) After inoculation the slide is placed in a specially designed germinating chamber (Eigsti, 1940c). This chamber is made of galvanized iron and constructed to hold slides over a water solution.

(9) The slide is kept in the chamber for at least twelve hours and usually not more than twenty-four hours. After this interval the preparation is ready for fixation, staining, and permanent mounting in balsam.

(10) The fixation and staining procedures can be outlined in eight steps, *viz.*, (a) stain in Belling's aceto-carmin fifteen minutes; (b) rinse in 45 per cent glacial acetic acid followed by a rinse in glacial acetic; (c) $\frac{1}{2}$ glacial acetic- $\frac{1}{2}$ tertiary butyl alcohol, ten minutes; (d) tertiary butyl alcohol, fifteen minutes; (e) $\frac{1}{2}$ tertiary butyl- $\frac{1}{2}$ xylol, ten minutes; (f) pure xylol, ten minutes, repeat this once; (g) mount in balsam.

This method provides slides with scattered metaphasic chromosomes in the pollen tube. In the region of the kinetochore the daughter chromosomes remain closely associated. However, at other points along the chromosome the separation is more or less complete; hence the length of chromosomal arms can be determined for each chromosome. It was possible to measure images of chromosomes by projecting a negative of the photomicrograph. This gave a magnification of $\times 17,500$. By means of a calibrated scale the actual lengths of chromosomes are expressed in microns (fig. 39–46).

Meiotic studies were made from aceto-carmin preparations of pollen mother cells, and these are illustrated by camera lucida drawings (fig. 30–33). Stomatal diagrams (fig. 37–38) were made from the photomicrographs of leaf portions of lower epidermis mounted in aceto-carmin. The illustrations of pollen grains were taken from ungerminated grains on slides used in chromosomal studies (fig. 34–36).

A 2 mm. apochromatic oil immersion objective and an $8\times$ compensating ocular were used in making the photomicrographs. A $10\times$ compensating ocular was substituted for the $8\times$ ocular in making the camera lucida drawings. The source of light was a Bausch and Lomb filament lamp and the light was filtered by a Wratten B filter No. 58.

OBSERVATIONS.—*The occurrence of tetraploidy.*—Tetraploid complements of representatives of *Polygonatum* are shown by photomicrographs (fig. 1–2, 5–9, 23–27) and the diploid complements are represented by figures 3–5, 10–22, and 28. Polyploidy was discovered when duplicate sets of chromosomes among the haploid complement of the pollen tube of

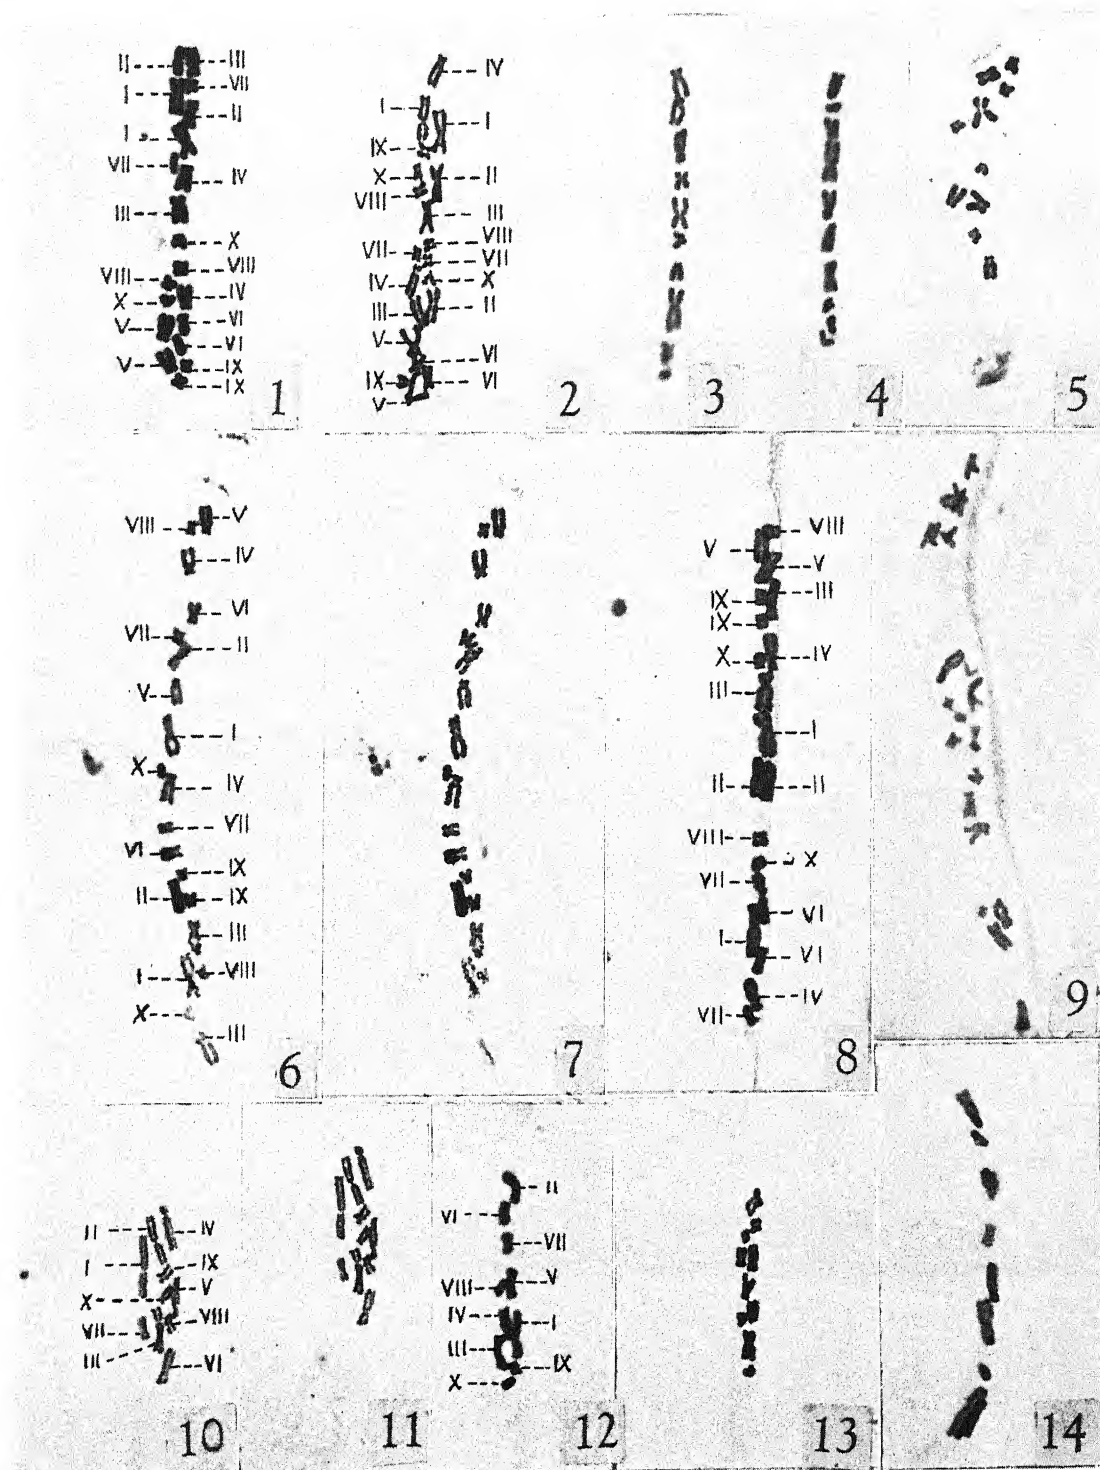

Fig. 1-14. Photomicrographs of chromosomes in pollen tubes of *P. canaliculatum* ($n=20$); *P. pubescens* ($n=10$); and *P. biflorum* ($n=10$); location of each collection given in table 2. All magnifications $\times 875$.—Fig. 1. Minnesota; Roman numerals indicate sizes and correspond to numerals elsewhere in figures where this collection is described; I-I are the largest pair while X-X are the smallest pair of homologous chromosomes; secondary association is shown by location of chromosomes with same numeral such as I, II, V, VI, VIII, IX, X.—Fig. 2. Oklahoma ($n=20$); 10 pairs of unseparated metaphasic chromosomes; secondary association of I, V, VI, VIII, IX.—Fig. 3. *P. pubescens*, Ohio, $n=10$.—Fig. 4. *P. pubescens*, Connecticut, $n=10$; two levels of focus.—Fig. 5. *P. biflorum*, Maryland, $n=10$; unusually

<i>P. canaliculatum</i>	20	..	Eigsti '40

P. canaliculatum were noted (Eigsti, 1940b) and when it was learned that this number represented a multiple of ten, the predominating number reported for the genus. As a matter of fact, a haploid number of twenty is not found in the published lists of numbers for species of this genus, whereas nine reports of ten chromosomes are recorded for the genus (Tischler, 1927, 1937, 1938; Matsuura and Sutô, 1935; Sutô, 1936; Cardiff, 1906; Cartledge, 1933). That pairs of homologous chromosomes do occur in the haploid complement is quite obvious if one uses enlarged photographs of individual chromosomes and arranges them in a series according to size from the largest chromosome I and I' to the smallest chromosome X and X' (fig. 23-27). Such duplication of pairs of homologues is not shown in diploid species (fig. 15-22). The individual chromosomes in certain figures can be located by means of Roman numerals adjacent to the chromosomes of the tetraploid (fig. 1, 2, 5-7), and diploid (fig. 10, 12, 13).

Colchicine prevents the formation of a metaphase plate, thus resulting in the scattering of unseparated daughter-metaphase chromosomes (fig. 1-14). This influence of colchicine is described in greater detail in previous papers (Eigsti, 1940a, 1940b). Nebel and Ruttle (1938) refer to the peculiar chromosomal formation as "ski-like." These formations are demonstrated in figures 15, 21, and 24. When reference is made below to "pairs of chromosomes," consideration is given only to homologous pairs of chromo-

somes characteristic of tetraploid complements such as chromosome I and I' of figure 24. The "pair" does not refer to the two daughter chromosomes associated together (fig. 24 I).

Throughout this study which involved numerous different plants of the genus, only two different haploid chromosomal counts were noted, *viz.*, ten and twenty (fig. 15-27). On the other hand Cardiff (1906) reported seven and eight for one American species *P. biflorum*; and among the entire list of chromosomes for *Polygonatum* (table 1) six other variations from ten and twenty are reported. Perhaps less variation of chromosome counts is to be expected when the present method of counting chromosomes from the pollen tube treated with colchicine is used. A record of chromosomal counts is presented in table 1 and the complete record of work for this present cytological survey is given in table 2.

Chromosomal morphology.—A scattered arrangement of chromosomes in pollen tubes treated with colchicine (fig. 1-14) facilitates studies of chromosomal morphology. The relative sizes of the arms of each chromosome are studied by comparing individual chromosomes of enlarged photomicrographs (fig. 15-27) as well as through measurements of chromosomes drawn to scale, with the length of each arm of the longer chromosome designated in microns (fig. 39-46). Because colchicine treatment accentuates the locus of primary constriction, or the kinetochore, a more accurate estimate of the lengths of the arms

good distribution of chromosomes.—Fig. 6-7. *P. canaliculatum*, Indiana, $n=20$; two levels of focus; chromosomes indicated by Roman numerals I to X and their corresponding pairs.—Fig. 8. Virginia, $n=20$; chromosomes unusually long.—Fig. 9. *P. canaliculatum*, Michigan; $n=20$.—Fig. 10-11. *P. pubescens*, New Hampshire, $n=10$; Roman numerals mark individual chromosomes; two levels of focus.—Fig. 12. *P. biflorum*, New Jersey, $n=10$; individual chromosomes labeled by Roman numerals; I is largest chromosomes and X the smallest.—Fig. 13. *P. pubescens*, Michigan, $n=10$.—Fig. 14. *P. pubescens*, Tennessee, $n=10$.

Summary:

Collections of plants from 25 localities:

P. canaliculatum (n-20) 13*P. pubescens* (n-10) 9*P. biflorum* (n-10) 3

—

25

and the morphology of the chromosome can be made using this reagent (fig. 15-27, 28, 29, 39-46).

Matsuura and Sutô (1935) list both primary and secondary constrictions among the complements of *P. humile* and *P. Maximowiczii*. They conclude for *P. humile* that there are seven chromosomes with sub-terminal, and three with sub-medial insertions, whereas the present study of complements from treated pollen tubes reveals six with sub-terminal insertions (fig. 28, III, IV, V, VI, IX, X), and four with sub-medial insertions (fig. 28, I, II, VII, VIII) among the species with a haploid complement of ten (fig. 15-22, 28); and twelve sub-terminal (fig. 29) and eight sub-medial insertions among those with a complement of twenty (fig. 23-27, 29).

In general there are six long chromosomes and four short ones in diploids (fig. 15-22, 28), and twelve long chromosomes and eight short ones in tetraploids (fig. 23-27, 29). Certain preparations show less tightly coiled chromosomes (fig. 10, 20, 24), and, because of this increased length, gradations of size are more easily recognized (fig. 20-24). A further classification of size is made by letters L, l, M, m, S, s, shown in figure 28; and L, L', M, M', m, m', S, S', s, s', are used to indicate homologous pairs of chromosomes in tetraploid plants (fig. 29). Individual chromosomes are indicated by Roman numerals (fig. 1, 2, 6, 8, 12, 10, 13, 14, 15-29, 39-46).

A study of the total length of individual chromosomes and the combined lengths of all chromosomes of a haploid complement is easier to make from the chromosomes in treated pollen tubes than from chromosomes found in the usual mitotic and meiotic stages. Of the four examples of diploid species measured (fig. 39-42) the average total length is 45.0 microns and the average for the four tetraploid species (fig. 43-46) is 83.8 microns. The latter figure is almost twice that of the former.

An idiogram of the tetraploid species was constructed from the average length of each arm of each chromosome (fig. 47) and the average length of each whole chromosome (fig. 47). A similar idiogram was made for the diploid species (fig. 48). The average total length of chromosomes of the five tetraploids measured is 81.1 microns (fig. 47) while the average total length of the chromosomes of seven diploids measured is 39.0 microns (fig. 48).

Of all the chromosomes measured in this study the longest was 11.5 microns (fig. 42 I), and the shortest 1.75 microns (fig. 41 X). Variability in size of individual chromosomes between different complements is noticeable, for instance, the chromosomes shown in figure 41 are much smaller than those represented in figure 42. A statistical analysis correlating the size of the plant with size of the chromosomes was not made; however, the largest tetraploid plant collected (table 2, no. 13) had the largest chromosomes (fig. 45), whereas the smallest tetraploid plant (table 2, no. 10) had the smallest total length of chromosomes (fig. 43). Darlington (1932) discusses the relation of the length of chromosomes to genotypic control. Recently Swanson (1942) re-

ported statistically significant size differences of chromosomes among different clones of plants belonging to the same genus. Further correlations between chromosomal size and characteristics of plants can be subjected to more intensive study with the present method of securing preparations.

Duplication of homologous chromosomes.—The chromosomal pairs of the tetraploid races often appear close together as shown by pairs I, II, V, VI, VIII, IX, and X in figure 1. A similar situation is found in figure 2 and to a limited extent this is true for chromosomes shown in figures 6 and 8. This is a case of secondary association of chromosomes. Since the cytoplasm is constantly moving in the pollen tube, there is opportunity for considerable rearrangement; in spite of this movement, the homologous chromosomes are often found close to each other.

Twenty distinct bivalents did not appear in the aceto-carmin preparations of meiosis in *P. canaliculatum* as found near Norman, Oklahoma (fig. 30-33). There is rather a grouping, or multivalent association (fig. 30-33). Cardiff (1906) noted difficulties in distinguishing the line of synapsis of the chromosomes in his studies of meiotic metaphases. Matsuura and Sutô (1935) reported ten bivalents for *P. Maximowiczii*, an Asiatic species; however, they mention that the "individual chromosomes are hardly discernible." The multivalent association (fig. 30-33) is indicative of homologies between the chromosomes of the duplicate sets, and further homology is brought out by a comparison of the pairs of enlarged chromosomes (fig. 23-27, chromosomes I-I', II-II', III-III', IV-IV', V-V', VI-VI', VII-VII', VIII-VIII', IX-IX', X-X').

Tetraploidy and the gigas complex.—The *gigas* characteristics associated with the tetraploid condition are quite obvious among those species with $2n=40$ chromosomes. As a rule the plants are more robust, the leaves are broader and thicker, the plants are greener, the rhizomes are more massive, the epidermal cells, especially the guard cells, are larger (compare fig. 37, a tetraploid, with fig. 38, a diploid), and the pollen grains of diploids (fig. 34) are smaller than the pollen grains of tetraploids (fig. 35-36). These are the usual quantitative morphological characteristics which differentiate diploid plants from natural and induced tetraploids (Müntzing, 1936). Müntzing (1932) states that "a characteristic feature of auto-polyploids is their vegetative vigor which is often striking enough to be called gigantism." *P. canaliculatum* ($2n=40$) is an excellent example of a species showing such *gigas* characters. However, tetraploid plants which are small and otherwise typical *biflorum* (table 2, no. 10) occasionally appear in the collections. While many characteristics point toward an autopolyploid condition, the present writer cannot conclusively prove this to be the case with the limited collection of plants and facts available. Systematists have recognized the morphological differences here found, as shown by their descriptions in the keys and manuals. Gates

Fig. 15-27. Enlargements of photomicrographs arranged in relation to size of chromosomes; largest chromosome on the left marked I in species with haploid number of ten and I-I' in species with $n=20$ chromosomes; certain collections shown in figures 1-14 represented; primary constriction appears unstained and in many cases marks the point where daughter chromosomes remain attached; differences in widths and length related to spiralization. All magnifications $\times 1,650$.—Fig. 15. *P. biflorum*, Maryland (fig. 5), twenty unseparated daughter chromosomes; four sub-medial chromosomes I, II, VII, VIII; six sub-terminal chromosomes, III, IV, V, VI, IX.—Fig. 16. *P. pubescens*, Minnesota;

Diagrammatic reconstruction of the chromosomal complement of *P. pubescens*, New Hampshire (fig. 10-11, 20); part of construction taken from photomicrograph and part from camera lucida drawing of the figure as it appears on the preparation; individual chromosomes are numbered by Roman numerals as in other figures; a more detail size classification is made by letters; L—largest, sub-medial insertion of the chromosome, l—next largest, sub-medial insertion chromosome; M—three medium sized chromosomes with sub-terminal insertions; m—next to medium size chromosomes with sub-terminal insertions; S—two small chromosomes sub-medial; s—two smallest chromosomes sub-terminal. $\times 750$.—Fig. 29. *P. canaliculatum*, Oklahoma (fig. 2, 24); reconstructed as figure 28; except for size of chromosomes of entire complement the general characteristics of chromosomes I-I', and others to X-X' are very similar to those in figure 28; size of chromosome by letter indicated through letters L-L', l-l', M-M', m-m', S-S', s-s'. $\times 750$.—Fig. 30-33.

chromosomes not distinct for arm length.—Fig. 17. *P. pubescens*, Connecticut (fig. 4); two levels of focus.—Fig. 18. *P. biflorum*, New Jersey (fig. 12); terminal attachment of X shown.—Fig. 19. *P. pubescens*, Michigan (fig. 13); small chromosomes; four sub-medial; six sub-terminal.—Fig. 20. *P. pubescens*, New Hampshire (fig. 10-11); loose spirals characteristic of this view; four sub-medial insertions I, II, VII, VIII; six sub-terminal insertions III, IV, V, VI, IX, X; six long chromosomes I-VI; four short chromosomes VI-X.—Fig. 21. *P. Pubescens*, Ohio (fig. 3); longest chromosome I appears much longer than the next largest size l.—Fig. 22. *P. pubescens*, Tennessee (fig. 14); six long chromosomes and four short.—Fig. 23. *P. canaliculatum*, Virginia (fig. 8); duplication of pairs of chromosomes marked by morphological features of the chromosomes; I-I' largest pair; V-V' particularly similar; also VI-VI', II-II'; twelve long chromosomes and eight short chromosomes.—Fig. 24. *P. canaliculatum*, Oklahoma (fig. 2); location of individual chromosomes in pollen tube figure listed in figure 2; similar morphology of pairs is shown especially in chromosomes I-I', IV-IV', V-V'; twelve long chromosomes and eight short chromosomes.—Fig. 25. *P. canaliculatum*, Minnesota (fig. 1); duplication of chromosomes in haploid complement shown by chromosomes I-I', II-II', III-III', IV-IV', V-V', VI-VI', X-X'; twelve long chromosomes and eight short ones; chromosome VII turned on edge.—Fig. 26. *P. canaliculatum*, Indiana (fig. 6-7); duplication shown by pairs of chromosomes.—Fig. 27. *P. canaliculatum*, Michigan (fig. 9); pairs of chromosomes in duplicate.

(1917) undoubtedly had a duplication of chromosomes in mind when he characterized *P. giganteum* as a mutant, and it must be recognized that several other plants in his classification were probably tetraploid. However, no cytological confirmation was reported in the literature.

DISCUSSION.—Speciation and polyploidy.—Because quantitative morphological characters are closely related to the problem of speciation, and because these are in turn associated with chromosomal differences taxonomists need all the cytological information possible before they can advance very far in their knowledge of species differentiation in this genus (Darlington, 1932). Cytological and genetical investigations of numerous workers have added much to our knowledge of species-formation in plants (Müntzing, 1932—*Galeopsis Tetrahit*; Huskins, 1930—*Spartina Townsendii*; Manton, 1935—*Nasturtium officinale*; Babcock, 1942—*Crepis*; and others). As a consequence of such cyto-genetic studies, the rôle of polyploidy in evolution is probably better understood than that of any other kind of hereditary change (Stebbins, 1940). Particularly helpful is the cytological information where systematists are confronted with closely intergrading forms which can be distinguished only by chromosomal differences. Often the sources of greatest vexation to the systematist provide the "keystone for evolutionary theory" (Dobzhansky, 1941). Speciation has occurred in *Polygonatum* through duplication of chromosomes. Accompanying this duplication, however, there are but few distinguishing qualitative characteristics which separate the diploid and tetraploid plants. Consequently it is difficult to make a satisfactory separation of species on the basis of taxonomic characters.

Cyto-taxonomy.—When polyploidy was discovered in the genus (Eigsti, 1940b) the bearing of this discovery upon taxonomic problems was obvious. Over two decades ago, Farwell (1915) pointed out

P. canaliculatum, Oklahoma; four views of first meiotic metaphase; in no figure are twenty bivalents distinguishable; homologies of chromosomes demonstrated by the association. $\times 875$.—Fig. 34. *P. pubescens*; diploid pollen grains; camera lucida drawing. $\times 245$.—Fig. 35-36. *P. canaliculatum*; tetraploid pollen grains; $\times 245$.—Fig. 37. *P. canaliculatum*; lower epidermis; $\times 100$.—Fig. 38. *P. pubescens*; lower epidermis; $\times 100$.

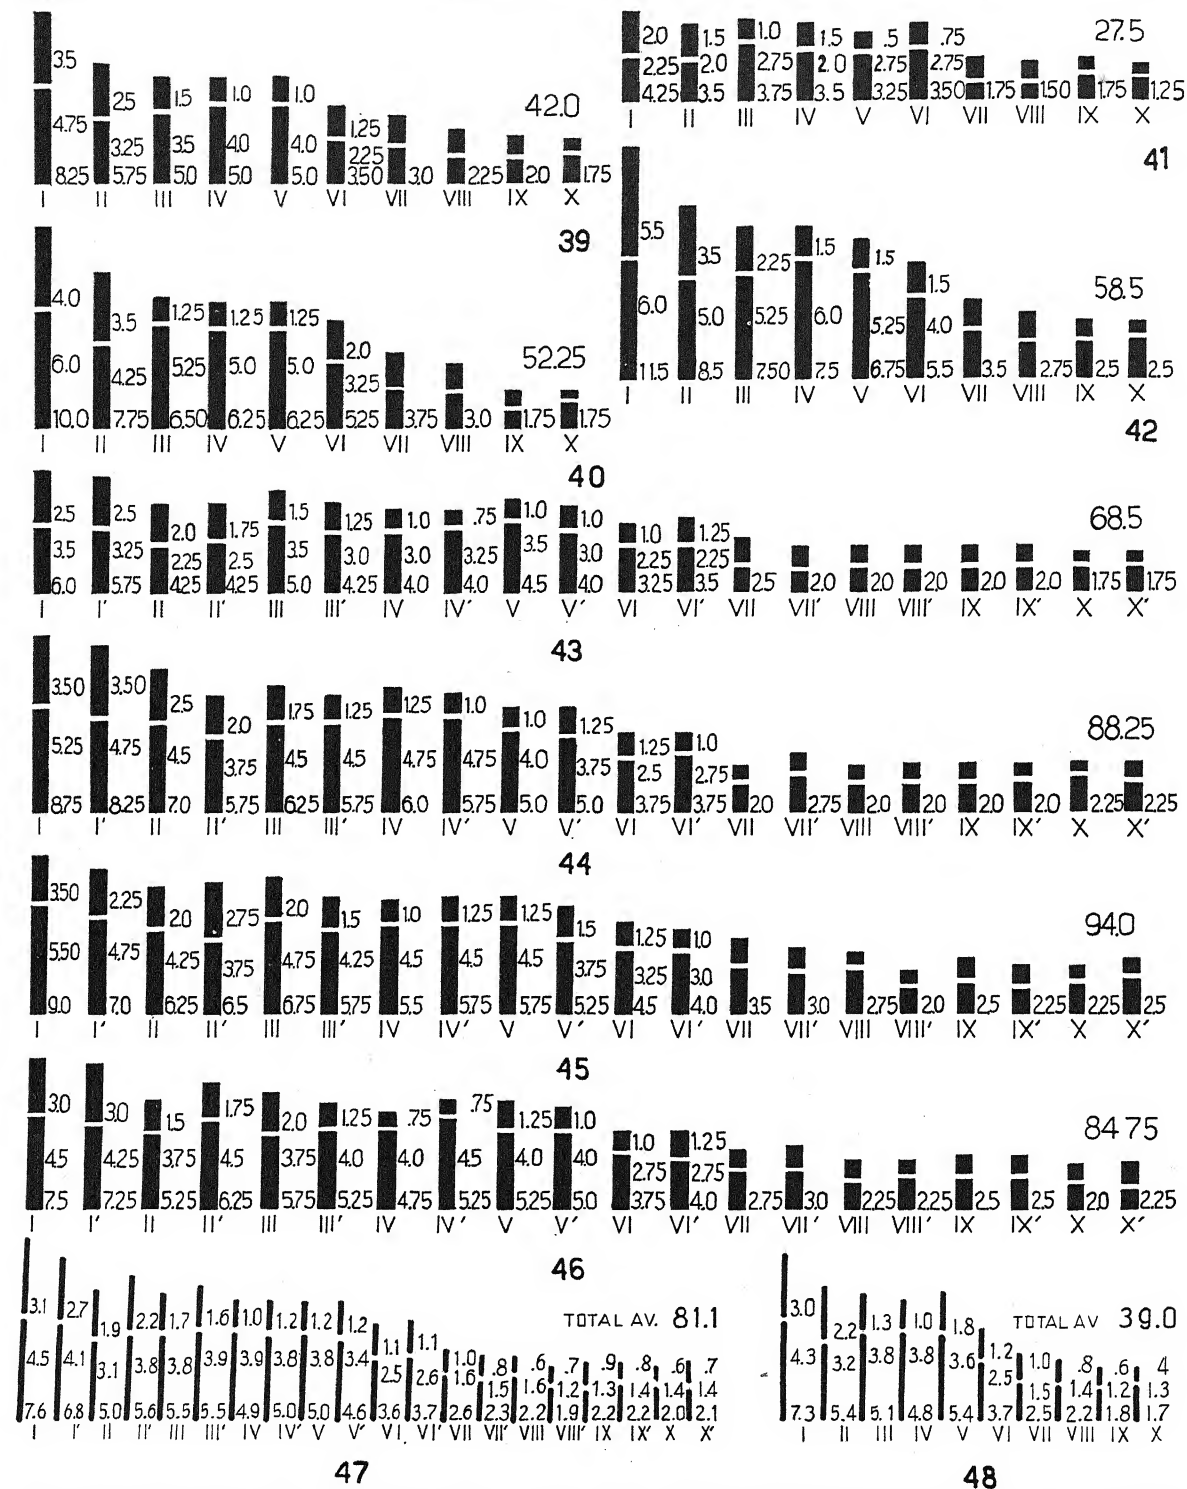

Fig. 39-48. Diagrammatic constructions from measurements of projected photomicrograph negatives magnified $\times 17,500$. The length of each arm of the chromosome listed for chromosomes I to VI; only total length listed for chromosomes VII to X; numbers at the right of each chromosome are as follows: top number is the short arm length; middle number lower arm; bottom number total length of the chromosome. Measurements from screen were made by a ruler calibrated to microns. Each micron equals 10 mm.; the white space marks location of kinetochore which separates the two arms of the chromosomes; total length of all chromosomes of a complement is listed above chromosome IX and X for each set.—Fig. 39. *P. biflorum*, New Jersey (fig. 18, 12).—Fig. 40. *P. pubescens*, Tennessee (fig. 22, 14); six long chromosomes, 5.25 microns or longer, four short chromosomes, 3.75 microns or shorter; total length 52.25 microns.—Fig. 41. *P. pubes-*

difficulties in classification of species in his monograph of the genus. Later Gates (1917) described the situation in this genus as "chaotic." Bush (1927) placed the problem among the unsolved ones in his study of the flora of Missouri and Deam (1940) records his observations and difficulties in dealing with the genus in Indiana.

Certain taxonomists have grouped all North American forms under *P. multiflorum* and others have admitted as many as twelve species (Farwell, 1915). Speciation from the cyto-taxonomic point of view, as shown by studies of plants from a number of localities (table 2), is best outlined under two distinct complexes separated by the presence or absence of foliar pubescence. The pubescent complex embraces the species *P. pubescens*, a diploid with $2n=20$ (fig. 3-4, 10-11, 17, 19, 20-22, 40-42). The glabrous complex includes two cytological types, *P. biflorum*, a diploid species with $2n=20$ (fig. 5, 13, 15, 18, 39), and *P. canaliculatum* with $2n=40$ (fig. 1-2, 5-9, 23-27). *P. canaliculatum* is a large plant with broad leaves clasping at the base and the *gigas* complex of characters, whereas the smaller species, *P. biflorum*, has narrow leaves, a smaller stature, and in general is a less sturdy looking plant. In the one manual used widely for this region (Gray's 7th ed.), only the diploid and tetraploid species are admitted, as *P. biflorum* and *P. commutatum*.² The third species, with foliar pubescence, found in many localities is omitted. Had the names *P. pubescens* and *P. canaliculatum* of the first edition been retained, much confusion could have been avoided.³ According to a study by Farwell (1928) there is a fourth species, *P. melleum*, with flowers honey yellow and distinct from the three species mentioned here. In the present cytological survey this species was unfortunately never procured. Future cytological analysis of this species is anticipated.

Distribution of species of Polygonatum.—Among the twenty-five collections (table 2) thirteen were classified as *P. canaliculatum*, nine as *P. pubescens*, and three as *P. biflorum*. Of the thirteen collections of *P. canaliculatum* eleven were analyzed cytologically as tetraploids, $2n=40$ (fig. 23-27, 43-46); of the nine *P. pubescens*, seven were diploids, $2n=20$ (fig. 16, 17, 19, 20, 21, 22, 40-42); and of the three *P. biflorum*, two were diploids, $2n=20$ (fig. 15, 16, 39). The tetraploids have a wider distribution and seem to be more abundant than the diploid plants. This observation is in harmony with previous

² Dr. W. A. Anderson, University of Iowa, Iowa City, Iowa, informs me in a personal communication that *P. canaliculatum* is a form of the plant which has been called *P. commutatum*.

cens, Michigan (fig. 19, 13); chromosomes short throughout complement, total 27.5 microns.—Fig. 42. *P. pubescens*, New Hampshire (fig. 10-11, 20); unusually long chromosomes, six long chromosomes and four short ones.—Fig. 42. *P. canaliculatum*, Minnesota (fig. 1, 24); short chromosomes throughout the complement; twelve long chromosomes differentiated from eight short.—Fig. 44. *P. canaliculatum*, Oklahoma (fig. 2, 25); twelve long chromosomes and eight short ones.—Fig. 45. *P. canaliculatum*, Virginia (fig. 8, 23); longest chromosomes measured; total 94.00 microns.—Fig. 46. *P. canaliculatum*, Indiana (fig. 6-7, 26); two classes of chromosomes, twelve long and eight short chromosomes.—Fig. 47. Idiogram of tetraploid constructed from the averages of the arms of chromosomes of five different complements.—Fig. 48. Idiogram of diploid involving seven measurements of different complements.

studies of geographic distribution of tetraploid plants (Müntzing, 1936; Stebbins, 1940).

Wiegand and Eames (1925) have made a study of *Polygonatum* as it occurs in the region of the Cayuga Lake Basin in northwestern New York. In this flora two forms of the glabrous complex occur, viz., one with elliptic, lanceolate leaves (probably a diploid), and the other with broad leaves and coarse, erect stems (tetraploid), found in rich soils. From their description it is possible that these plants are examples of cytologically different forms which are not easily distinguishable taxonomically. In Indiana (Deam, 1940) the tetraploid (table 2, no. 13, fig. 26, 36, 46) is found along roadsides, and what is probably the diploid (*P. biflorum*) is from wooded areas. These differences in habitat are probably the result of the different physiological characteristics of diploids and tetraploids.

The seeds of all species are disseminated by birds, since the fleshy fruit is attractive to and eaten by them (Deam, 1940). Once a seedling is established in a new territory, the one with most vigorous vegetative propagation survives under the more adverse conditions and thus in a greater variety of situations. In this case the tetraploid, *P. canaliculatum*, is able to survive because these plants are robust and hardy and more easily propagated vegetatively. Deam⁴ finds that when the diploids and the tetraploids are established in a garden, the latter is more difficult to eradicate. Perhaps another factor to be considered is that tetraploids frequently exhibit greater variation in vigor than the corresponding diploids. Stebbins (1942) observed a greater variation in vigor among tetraploid progeny of *Stipa lepida* Hitchc. than among diploid. It seems plausible that the wider distribution and greater abundance of *P. canaliculatum* is probably due to these factors.

The diploid species is in flower earlier than the tetraploid species. In the garden at the University of Oklahoma diploid species flower about three weeks earlier than the tetraploids growing under similar conditions. Such differences in relation to physiological changes accompanying polyploidy are discussed by Stebbins (1940). A difference in period of flowering becomes a factor of great significance as an isolation mechanism between the diploid and tetraploid races. Furthermore, the different ecological relationships tend to isolate the species in different environmental areas.

SUMMARY

A cytological investigation of colchicine-treated pollen tubes of *Polygonatum* has been made.

³ This information was kindly contributed in a letter from Dr. W. A. Anderson.

⁴ Personal communication.

Duplication of sets of chromosomes in tetraploid plants was confirmed by comparison of the sizes of the various chromosomes of the complement and by the occurrence of a multiple series of chromosome numbers.

Colchicine facilitates the studies of chromosomal morphology because the chromosomes are straight and the region of the kinetochore is quite distinct. The scattered chromosomes of treated pollen tubes are easier to study as individual units.

In diploid species there are six sub-terminal and four sub-medial chromosomes; in tetraploids there are twelve and eight respectively. In general there are six long chromosomes and four short ones in diploids. In tetraploids there are twelve long and eight short chromosomes. Further size classification is made, using the letters L, l, M, m, S, and s. Individual chromosomes are indicated by Roman numerals.

The average total length of the chromosomes of seven complements among diploid species was 39.0 microns; the average of five tetraploid complements was 81.1 microns. The longest chromosome measured was 11.5 microns and the shortest 1.25 microns.

Secondary association was apparent in tetraploid complements. Further evidence of homologies among chromosomes of the tetraploid was secured from the

multivalent associations in meiotic studies in the Oklahoma collections.

The so-called *gigas* characters were found in *P. canaliculatum*, the tetraploid species. These characters which differentiate the diploid species from the tetraploid are quantitative rather than qualitative. Speciation has occurred by duplication of chromosomes in the genus *Polygonatum*. The polyploid series was found in the glabrous complex of this genus. *P. biflorum* is the diploid ($n=10$) and *P. canaliculatum* ($n=20$) is the tetraploid; both were found to be glabrous plants.

Tetraploids are more widely distributed than diploids. Increased hardiness, greater vigor and tendency toward more vegetative propagation in tetraploids are apparently factors responsible for the distributional differences between diploid and tetraploid species.

When both species are found in the same region, the diploid plants flower about one month earlier than the tetraploid plants, which is considered to be an important factor in the isolation of species of this genus.

AUTOPOLYPLOIDY AND GEOGRAPHICAL DISTRIBUTION IN *CUTHBERTIA GRAMINEA* SMALL¹

Norman H. Giles, Jr.

THE RELATIVE rôles which various kinds of genetic change have played in the evolution of species continue to be of great interest to the cytogeneticist (Dobzhansky, 1941) and are increasingly being recognized as of fundamental concern to the systematist (cf. Huxley, *et al.*, 1940). Allopolyploidy is generally recognized as having been of exceptional importance as an evolutionary mechanism in the higher plants. The question of the relative significance of autopolyploidy, however, is not as well settled (Stebbins, 1940), although Müntzing (1936) and others have presented evidence indicating that it is probably of considerable consequence. The purpose of the present paper is to report some of the results of a study of intraspecific autopolyploidy in *Cuthbertia graminea*. The evidence in this case indicates that autopolyploidy has profound morphological and physiological effects on the individuals in which it occurs, and further, that it has resulted in striking changes in the composition of the natural populations of this species complex. It seems clear that the advantages resulting from autopolyploidy have been so considerable that autotetraploids now constitute a very large fraction, numerically and geographically, of the individuals in this taxonomic species.

THE TAXONOMY AND CYTOLOGY OF CUTHBERTIA GRAMINEA.—The genus *Cuthbertia* was erected by Small (1903) to include a homogeneous group of species in the Commelinaceae, which, though closely related to the well-known spiderworts of the *virginiana* complex of *Tradescantia* L., are clearly dis-

tinct. The genus as now recognized (Small, 1933) includes the three species *C. graminea*, *C. rosea* (Vent.) Small, and *C. ornata* Small. *Cuthbertia* is separable from *Tradescantia* on morphological, geographical, and cytogenetical grounds. Such differences have been pointed out by Anderson and Woodson (1935) and Anderson and Sax (1936), even though the former authors retain the species of *Cuthbertia* as varieties of *T. rosea* Vent. in their taxonomic monograph of species of *Tradescantia* occurring within the United States.

The only previous description of the chromosome complement for a species of *Cuthbertia* is that given by Anderson and Sax (1936), who found the somatic number of *graminea* to be twenty-four—eight chromosomes with approximately median, and sixteen with sub-terminal centromeres. The meiotic behavior was described as regular and the amount of visibly normal pollen as high. It has since become evident from the present studies that the plant which they examined must have been an autotetraploid, and that diploids and autohexaploids also exist in *graminea*. An examination of several specimens of *rosea* has so far revealed only diploids.

The types of chromosomes composing the basic complement of *C. graminea* are particularly clear at mitosis in the pollen grain (fig. 1 and 2). It is evident that four of the chromosomes have subterminal centromeres and two approximately median ones. Studies of chromosome pairing at meiosis in the three cytological forms which have been found to occur in this species have given the following results: in the diploids, six bivalents are regularly present at metaphase; in the tetraploids, bivalents and quadrivalents are the rule; while in the hexaploids, bivalents, quadrivalents, and hexavalents occur. In the somatic cells of the tetraploid, each of the chromosomes of the basic set is seen to be represented four

Fig. 1-2.—Fig. 1 (left). Haploid set of chromosomes of *Cuthbertia graminea* (2x) at metaphase of first post-meiotic (microspore) mitosis. $\times 1,000$.—Fig. 2 (right). Diploid set of chromosomes of *C. graminea* at the microspore division of an autotetraploid (4x). $\times 1,000$.

times, in a hexaploid each is represented six times. These observations provide cytological evidence for autopolyploidy. Further evidence is supplied by the fact that the polyploids are quite comparable morphologically to the diploids, except that they possess the "gigas" characteristics often associated with autopolyploidy (Müntzing, 1936). Also the diploids themselves are fully fertile and show no evidence of hybrid ancestry, as would be expected were the derived forms allo- rather than autopolyploids. A detailed cytological analysis, particularly of meiotic behavior in the three forms, will be deferred until a later paper.

It is clear that there are considerable differences between the chromosome complements of the species of *Cuthbertia* and those of the species of *Tradescantia* in the *virginiana* complex, since the latter have chromosomes all of whose centromeres are approximately median. These differences, together with the evidence from morphology and geographical distribution, imply a considerable genetic divergence of the two groups. It is not surprising under the circumstances, then, that extensive attempts which have been made during this study to make hybridizations between various species of the two genera have been unsuccessful.

In geographical distribution, the species of *Cuthbertia* are found in the South Atlantic Coastal Plain region (and rarely in the adjacent Piedmont province), from southeastern Virginia (Fernald, unpubl.) to southern Florida (Anderson and Woodson, 1935). Only *graminea* is found throughout this entire area, *rosea* occurring in the region north of Florida, and *ornata* only within the limits of that state.

COMPARISON OF THE DIPLOID AND POLYPLOID FORMS.—It has been pointed out by Anderson and Sax (1936) that the diploid and autotetraploid forms which occur in several species of the *virginiana* group of *Tradescantia* usually cannot be distinguished by gross size differences, although some general differences can be detected when the two forms have been identified cytologically. In the present case, however, there are considerable size differences between the diploids and the tetraploids of *C. graminea*, the latter being distinctly larger on the average. These differences are brought out in table 1 which records measurements of individuals whose chromosome numbers were known. For measure-

ments of leaf length and width, the maximum values found on a given plant were used to bring out the fact that on the average the organs of the tetraploids attain a considerably greater size than those of the diploids. The values for corolla diameter and sepal length are averages of several flowers from the number of plants indicated. In all the types of measurements for which standard errors have been calculated the differences between the means for the two types are highly significant. It is clear that diploids and autotetraploids vary in size of entire plants and plant organs about quite distinct means. Other measurements have indicated differences in stomatal size and number per unit area of leaf, and in pollen grain size, as would be expected. Studies in the field have shown that the tetraploids are in general much more vigorous plants than the diploids. The size of the tetraploid plants is considerably larger, and there are usually several stems per plant, whereas in the diploids there are usually only one or a few stems. Another indication of the greater vigor of the tetraploids is derived from comparisons of the two types growing under comparable greenhouse conditions. Here it has been found that the diploids show a much higher mortality than the tetraploids. The tetraploids flower more profusely than the diploids, and both types set seed readily in the field in most cases, even though preliminary studies in the greenhouse indicate that self-sterility is usually present, as is the case in the species related to *T. virginiana*. Propagation appears to be largely by seed rather than by vegetative means. There is some evidence from field observations that in the same latitude the diploids flower earlier than the tetraploids and probably have a shorter blooming season. Figure 3 shows a comparison of a diploid and an autotetraploid. These two plants were transplanted from the field to the greenhouse and are quite typical of the size differences found under natural conditions. In this connection, it is interesting to note that this size difference has led to some confusion among taxonomists, who have upon occasion identified the tetraploids of *graminea* as *rosea* because of their wider leaves. To one who is familiar with both species, however, the differences between even a tetraploid *graminea* and a diploid *rosea* are obvious at a glance.

It has not been possible to secure enough measurements on the hexaploids to permit adequate comparisons, since only two plants of this type were

TABLE 1. Comparative measurements of diploids and tetraploids of *Cuthbertia graminea*.

Character	Tetraploids			Diploids		
	Mean (mm.)	S. E.	No. plants measured	Mean (mm.)	S. E.	No. plants measured
Height of plant	205.0 \pm 4.4		53	158.0 \pm 4.6		18

Corolla diameter (average)	20.0		20	16.8		6
Sepal length (average)	5.3		20	4.3		6
Seed length	1.95 \pm 0.03		50 (seeds)	1.45 \pm 0.02		50 (seeds)
Seed weight (average)	1.48 mg.		162 (seeds)	0.73 mg.		176 (seeds)

TABLE 2. Somatic chromosome numbers found in *Cuthbertia graminea*.

	2n	Counts obtained at meiosis or in root tips				Plants collected	
		2n+1	Per cent	2n+2	Per cent	No. of localities	No. of plants
Diploids (2n=12)	13	0	0.0	0	0.0	12	28
Tetraploids (2n=24)	73	2	2.7	0	0.0	47	134
Hexaploids (2n=36)	1	0	0.0	1	50.0	2	2

available. However, it is clear from general observations that the hexaploids also show gigas characteristics, and in size of certain plant organs are larger than the tetraploids. They also appear to develop more slowly under greenhouse conditions. It is of interest to note that the first hexaploid found was specifically selected from among a population of tetraploids in the field because of the distinctly larger size of its buds and flowers.

SOMATIC CHROMOSOME NUMBERS.—In studying the cytology of three forms, an effort was made to obtain data on the prevalence of aneuploidy under natural conditions. Many of the preliminary counts made to determine the presence of polyploidy in plants collected in the field were based on studies at the microspore division, but these observations cannot be used with certainty to indicate the presence or absence of aneuploid types. Consequently, in as many plants as possible counts were obtained at meiosis; in a few, root-tip mitoses were used. The results are summarized in table 2. In the diploids, although the numbers are small, there were no cases of $2n+1$ types. It should be noted as well that, for plants in which counts were obtained at the microspore division only, there was no evidence of an excess of pollen grains with $n+1$ chromosomes. Probably all the twenty-eight plants had the basic number of twelve. In the tetraploids, however, of the seventy-five plants for which definite counts were obtained, two (2.7 per cent) were $4x+1$. In both exceptional plants one of the shorter chromosomes having a subterminal centromere was present as the

extra member of the complement. Only two hexaploids were obtained from collections in the field, but one of these had two extra chromosomes (both with subterminal centromeres) present.

ECOLOGICAL DISTRIBUTION.—The three species of *Cuthbertia* differ in their ecological distribution. The writer is familiar from field experience with only *C. graminea* and *C. rosea*, particularly the former. *Cuthbertia rosea* occurs in semi-mesic areas, such as oak woods, having a soil containing appreciable quantities of humus. On the other hand, *graminea* is

typically a plant of definitely xeric areas of almost pure white sand. According to the description of ranges in Small (1933) and Anderson and Woodson (1935), *ornata* is found in the Florida "scrub," which is apparently a fairly distinct and characteristic plant association.

The localized ecological habitat to which *graminea* is largely restricted is commonly termed the "sandhills" whether it occurs in the more typical region of the Fall Line sandhills, or in other areas of the coastal plain near the coast, where this habitat is found particularly along stream borders. These sandhill areas are characterized not only by their coarse white sand with its accompanying extreme aridity, but also by a typical plant association. The distinctive members of this vegetation-habitat complex are the wire grass *Aristida stricta* Michx., the Turkey oak *Quercus laevis* Walt. (= *Q. Catesbaei* Michx.), and the longleaf pine *Pinus australis* Michx. f. (= *P. palustris* Mill.).² Throughout the

southeastern region of the Coastal Plain from North Carolina to Florida the dominant members of this association remain the same, although certain of the other less characteristic species vary from place to place. A good description of this plant community as it occurs in the sandhill region of the southwestern area of the Coastal Plain in North Carolina is given by Wells and Shunk (1931).

To furnish some idea of the plants found associated in the field with *graminea*, table 3 lists some of the species observed in representative areas where collections of this species were made. The first of these areas was visited on June 1, 1940. The locality is one typical of most of the North Carolina "sandhill country" and is located about two miles southeast of Spout Springs. Diploid plants of *graminea* were collected at this spot. The second locality is on

² In all matters of nomenclature Small's Manual (1933) will be followed.

the east bank of the Canoochee River in Bryan County, Georgia, an area typical of the sandhills of the lower terraces of the Coastal Plain nearer the sea. It was visited on September 11, 1939, at which time tetraploid plants of *C. graminea*, which had apparently finished blooming for the year, were collected. A photograph of this area, taken by Mr. Ivan Tompkins on February 25, 1940 (fig. 4), gives a good idea of the physical appearance of the sandhill type of habitat. The third locality is about five miles east of Aiken, South Carolina, on U. S. highway 1 where several tetraploids and one hexaploid plant of *graminea* were collected. This area was visited on June 28, 1940, and again on April 11, 1941. The soil at this spot, though quite sandy, is considerably grayer in color than that in the more typical areas and contains more humus. The vegetation is also somewhat different, being less xeric in character. As will be noted in table 3, oaks other than *Q. laevis* were present. The two other species noted, *Q. Margaretta* and *Q. marilandica*, occur in the xero-mesic phase of the sandhill succession as shown by Wells and Shunk (1931). The collection of tetraploids of *graminea* in this habitat and at other similar stations throughout the range of this form is of considerable interest, since it indicates a greater ecological amplitude of the tetraploids. Even though both forms are characteristically found in the typical sandhill habitat, the diploids are apparently more restricted in their ecological distribution.

One particular advantage in using *C. graminea* in a study such as the present one should be mentioned here, for it is a direct consequence of the ecological peculiarities of the species. Since this plant is a member of a vegetation-habitat complex restricted largely to sterile soils, for the most part unfit for agriculture, the species has been subjected to almost no human interference. This fact permits an interpretation of the past history of the species to be made from present observations with considerable assurance that it has not been unduly complicated by recent artificial environmental changes. In this respect the situation is more satisfactory in *Cuthbertia* than in *Tradescantia*, for the natural habitats of many of the species in the latter genus have been seriously modified by man (Anderson and Hubricht, 1938). Such a condition tends to distort the results obtained from a study of "natural" populations.

GEOGRAPHICAL DISTRIBUTION OF THE CYTOLOGICAL FORMS.—The first collections of *C. graminea* were all tetraploids, but, during the summer of 1939, diploids were discovered by Dr. Carl Swanson and Dr. Thomas Kerr in the sandhill country of the North Carolina Coastal Plain. As more plants were collected and examined cytologically, it began to appear that the diploid and tetraploid forms occupied distinct areas. In order to be certain of this difference, and to delimit, in so far as possible, the respective ranges of the two forms, an extensive collection of living material was made on the South Atlantic Coastal Plain and grown at the Arnold Arboretum.

TABLE 4. Data on collections of *Cuthbertia graminea*. Under location, the distance and direction from the point of reference are usually given; numbers refer to federal (U. S.) and state highways along which many of the collections were made. Abbreviations of collectors' names are explained in the text.

^a 1=4x+1. ^b Data from Anderson and Sax (1936).

The data on these collections are given in table 4. A name has been assigned to each collection. The number of plants in the collection is then given, followed by the chromosome number, the approximate geographical location, and the collector's name. In some cases chromosome counts have been obtained from preserved material also. In all but two instances, however, these preserved collections were made along with living plants. The collections are arranged with the localities of the diploids first, alphabetically, followed by the localities of the tetraploids in geographical order, going from north to south. To simplify the table, abbreviations for certain collectors' names have been used. These are as follows: Dr. Thomas Kerr=K.; Dr. Carl Swanson=S.; Mr. Don Eyles=E.; Mr. H. A. Rankin=R.; the writer=G. To all those who have collected specimens, the writer is greatly indebted, and especially to the four mentioned above who have expended considerable time and effort in so doing. As yet, no search has been made for stations of *graminea* in the Piedmont province adjacent to the Fall Line, but if the plants do occur in this province they must be relatively rare, as indicated by the citations of specimens by Anderson and Woodson (1935).

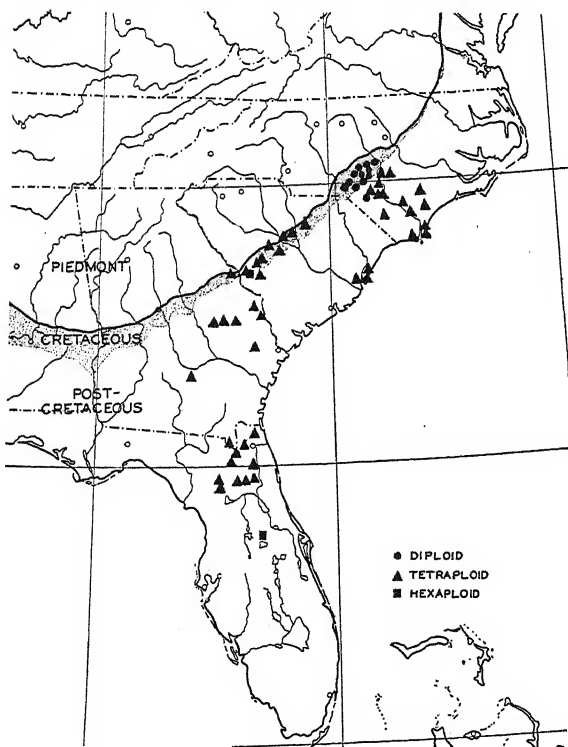

Fig. 5. The distribution of the three cytological forms of *C. graminea* on the South Atlantic Coastal Plain. The heavy black line indicates the position of the Fall Line, the inner limit of the Coastal Plain sediments. The stippled area indicates the extent of surficial deposits of Cretaceous age; the unstippled area east and south of the Fall Line represents surficial deposits of post Cretaceous, primarily Pleistocene, age. Based on Goode Base Map No. 209E. By permission of the University of Chicago Press.

The localities where the collections were made have been indicated on the accompanying map (fig. 5). It is immediately clear that the diploids are restricted to a relatively small area in North Carolina, the tetraploids occupy a much more extensive area throughout the South Atlantic Coastal Plain, and the hexaploids have been found at only two widely separated stations. It also appears that the diploids and tetraploids do not occur in the same area. With a single exception (plants collected near Rennett in Robeson County, North Carolina) all the diploids are confined to the typical sandhills along the western edge of the Coastal Plain in North Carolina. In no case have diploids and tetraploids been found growing together in the field. A single triploid plant was obtained at the Hoke County Line station in North Carolina. It is worthy of note that this locality is apparently just on the boundary between the diploid and tetraploid areas. The hexaploid from the Aiken (South Carolina) station, however, was found growing in the middle of a large tetraploid population.

DISCUSSION.—It is clear from the preceding evidence that the advent of autopolyploidy has profoundly modified the composition of the natural population known taxonomically as *Cuthbertia graminea*. The autotetraploids are found to differ from the ancestral diploids in a number of important respects. Morphologically they exhibit gigantism, and there are also preliminary data indicating that they have a greater variability. Physiologically they appear to be more vigorous. Cytologically they are more variable, as shown by the presence of extra-chromosomal types. Unpublished studies also indicate a greater frequency of structural changes in the chromosomes of the tetraploids. Factors such as the above are presumably the basis for the distributional differences characterizing the two forms. From an ecological point of view, there is evidence suggesting that the tetraploids can occupy more diverse habitats than the diploids. Further, there is the striking difference in geographical distribution.

From the cytological and distributional data which are now available, together with a knowledge of the geology of the region under discussion, it is possible to obtain a fairly clear picture of the past history of the *graminea* complex and to make at least a preliminary evaluation of the rôle of autopolyploidy in its development.

Briefly, the geological history of this area is as follows: The entire South Atlantic Coastal Plain is underlain by sedimentary deposits ranging in age from Upper Cretaceous to Recent. The older deposits are those immediately adjacent to the Fall Line, which marks the limit of the crystalline Piedmont province. Deposits successively younger in age occupy the region between the Fall Line and the coast, a very considerable proportion of these being terraces of Pleistocene origin. On the map (fig. 5) the extent of the surficial deposits which are considered to have originated primarily from the weathering of the Upper Cretaceous sediments is indicated.

The data on which these limits are based have been obtained from Stephenson (1912), Cooke (1936), and Fenneman (1938). The North Carolina sandhills, which were formerly included in the Lafayette formation (Stephenson, 1912), are now considered to be composed of the weathered residual products mainly of the Tuscaloosa formation (Upper Cretaceous) and subordinately of the Paleocene (Cooke, 1936; Stephenson, 1940). This region adjacent to the Fall Line has probably not been submerged by the sea since early Tertiary at the latest.

There is a notable correlation between the geological evidence and the geographical facts. The diploids occupy an area geologically older than that in which most of the tetraploids occur. The obvious interpretation is that the North Carolina sandhills represent entirely or in part the original area occupied by the ancestral diploids and their descendants, and that the derived autotetraploids, being more vigorous and aggressive, have been almost entirely responsible for the colonization of lands as they became available following the retreat of the sea within relatively recent times.

Another question of considerable interest concerns the possibility that the more vigorous tetraploids have been able to replace the original diploids over some or a considerable portion of their range. Under such circumstances the present diploid area would represent only a certain fraction of that formerly occupied by diploids. It is not possible at present to answer this question definitely, but certain preliminary evidence indicates that such a replacement may have occurred. The first collections of *C. graminea* were tetraploids from the Pleistocene terraces of North Carolina and Georgia. When the diploid area was discovered in North Carolina, it was assumed that diploids would also be found in the Fall Line sandhills of South Carolina and Georgia. However, fairly extensive recent collections from Augusta to Columbia and Camden have revealed only tetraploids in this area. As yet no specimens have been secured between Camden, South Carolina, and the North Carolina sandhills, so that it is not yet possible to define the southern limit of the diploid area. On the basis of the present evidence, however, it seems possible that the tetraploids may have been able to supplant the diploids in a part of their original range along the Fall Line. On the other hand there may be certain geological or ecological differences between these two adjacent sandhill regions which account for the limited range of the diploids, but as yet no such differences have been detected. More field study and the collections are necessary before this point can be determined. Such evidence will be of further value, since it may make possible an estimate of the time of origin, geologically, of the tetraploids.

It is not yet possible to draw definite conclusions as to the evolutionary significance of the autohexaploids, since only two of these have been discovered so far. The fact that they have proved so rare, and that the two individuals were collected at wholly

unrelated localities (Aiken, South Carolina, and central Florida) indicates that they are probably sporadic forms which may occur with a low frequency in any tetraploid population. This low population frequency itself suggests that their increased chromosome number has somehow resulted in decreased selective advantages, at least in competition with their tetraploid ancestors. However, it is not impossible that the hexaploids are of very recent origin and may be in the process of becoming established as an element in the natural population at the present time. As yet this possibility cannot be eliminated and a decision must await further evidence.

A difference in range between diploid and autotetraploid intraspecific races has been noted previously in several plant species. An example which is similar in several respects to the one being discussed here is that reported by Manton (1934, 1937) for *Biscutella laevigata* L. In this species the diploid forms ($2x=18$) are restricted to the unglaciated river valleys of Central Europe, whereas the tetraploids ($4x=36$) occur in nearly the whole area occupied by the Alpine Ice sheet during the Glacial Period. The evidence indicates that the diploids are waning inter-glacial or pre-glacial relics, and are not expanding their territory, whereas the tetraploids are vigorous post-glacial immigrants to many of their present districts and may still be spreading. An autohexaploid form ($6x=54$) also occurs in northern Spain and appears to be separated geographically from the rest of the complex.

The tetraploids of *B. laevigata* also differ from the diploids in being cytologically unstable, almost 20 per cent having somatic chromosome numbers other than the expected thirty-six. Further, they have the capacity to propagate themselves vegetatively as is often the case in forms possessing unbalanced chromosome complements. By way of contrast *C. graminea* has been found to be relatively stable cytologically, since, as indicated in table 2, less than 3 per cent of the plants from a sample of similar size to that taken in *Biscutella* were aneuploid types. A difference in the methods of collecting the data in these two cases should be pointed out, however. The chromosome numbers found in *graminea* were all obtained from mature plants collected in the field. These plants had consequently been subjected as seedlings to natural selection. For *Biscutella* most of the counts were obtained from seedlings grown in the greenhouse from seeds collected in nature. The difference in the cytological stability is very probably a real one, however, and might be expected, since the degree of unbalance in a $4x+1$ aneuploid having a base number of nine would presumably be less than in one with a base number of six. It is also worthy of note as a correlation with the lower frequency of aneuploids that propagation in *C. graminea* occurs almost exclusively by seed, and not by vegetative means.

Intraspecific autopolyploidy has been demonstrated in several species of the *virginiana* complex of the closely related genus *Tradescantia* (Ander-

son and Sax, 1936; Anderson and Woodson, 1935; Anderson, 1937). In this case the area of the combined ranges of the tetraploids is considerably greater than that of the diploids, and the diploid forms occupy a region which is geologically old and has been continuously open for plant habitation. It is significant that even though considerable genetic divergence separates the two genera *Cuthbertia* and *Tradescantia* the intrageneric evolutionary patterns of the two seem to be basically similar.

In *Tradescantia* it is apparent that the spread of the more successful tetraploids has been primarily to the northeast and northwest from a center of distribution near central Texas. Conversely, in *Cuthbertia graminea* this spread has been largely southward. These observations are of some interest in connection with studies (cf. Tischler, 1935; Flovik, 1940) showing that the percentage of species with high chromosome numbers is greater in the flora of Northern than of Southern Europe. Many of these species are undoubtedly allopolyploids, but it also seems true that in cases of intraspecific autopolyploidy the tetraploids have as a rule a more arctic or alpine distribution than the diploids (Müntzing, 1936). These observations have been interpreted as indicating a relation between climate and distribution of the tetraploids, the explanation being that these presumably more vigorous types could occupy areas in which the diploids were not able to survive. However, it seems clear from the two cases cited that the direction of spread is probably not conditioned as much by the presence of a more rigorous climate as by the availability of new territory for plant occupancy. It is apparently of no great importance whether territory becomes available for plant occupancy as a result of the retreat of glaciers to the north or of seas to the south; in any case the tetraploids, if more vigorous, will do the colonizing. The restriction in northward spread of the tetraploid *C. graminea* has apparently been due in large part to the lack of habitats adapted to the relatively strict ecological requirements of the species.

CONCLUSIONS.—Autopolyploidy has been a factor of major importance in the evolution of the *Cuthbertia graminea* complex. The profound physiological consequences of polyploidy have enabled the tetraploids to effect a great expansion of the range of the species ecologically, and especially geographically, by colonizing new territory, most of which has become available for plant occupation in relatively recent (Pleistocene) times. The ancestral diploids have been left behind as a small relic population in an area geologically old (Cretaceous). Further, there is some evidence suggesting that the tetraploids may have displaced the diploids from a part of the latter's original range. If such a process of replacement has actually occurred and continues, the result should be the complete elimination of the diploids, and eventually the species would be represented in nature only by the derived polyploids.

It is not yet possible to evaluate fully the significance of the rare and sporadic occurrence in natural

populations of individuals showing still higher degrees of autopolyploidy (hexaploids). The fact that the hexaploids have not become a distinct and numerically significant element in the population may indicate that the advantages resulting from an increase in chromosome number are diminished or lost in this species complex above the tetraploid level. The two hexaploids so far discovered would then presumably represent fortuitous cases of autopolyploidy which might be expected to occur occasionally in almost any plant population. However, another interpretation of the hexaploids seems possible. It may be that their high degree of polyploidy is of very recent origin, and that this cytological form is even now in the process of becoming established as a new and important element in the population.

SUMMARY

Intraspecific natural autopolyploidy is shown to occur in *Cuthbertia graminea*. Wild populations of this taxonomic species include diploids, autotetraploids, and autohexaploids. The base number of the species is $x=6$; four of the chromosomes of the haploid set have subterminal, and two median centromeres.

The genus *Cuthbertia* is rather closely related to the *virginiana* species complex of *Tradescantia*. However, the striking differences in chromosome morphology of the two groups imply a considerable genetic divergence, and this is supported by purely genetic evidence, since numerous attempts to make hybrids between species in the two groups have failed.

A comparative study of the diploids and autotetraploids of *C. graminea* has revealed that the two types differ strikingly in several respects. These differences are as follows:

(a) Morphologically the tetraploids exhibit considerable gigantism; physiologically they are characterized by greater vigor, both in the field and in the greenhouse.

(b) Cytologically the tetraploids are more variable. Two plants out of seventy-five examined (2.7 per cent) were aneuploids ($4x+1$), whereas no aneuploids have been found among the diploids.

(c) Although both forms are largely restricted to xeric sandhill habitats of the Coastal Plain, there is evidence that the tetraploids possess greater ecological amplitude.

(d) Perhaps the outstanding difference is one of geographical distribution. Extensive collections and examinations of living plants have shown that the diploids are restricted to a relatively small area in the Fall Line Sandhills of southern North Carolina, whereas the tetraploids occupy an extensive area throughout the remainder of the Coastal Plain.

The ecological restriction of *C. graminea* to xeric sandhill habitats makes this species particularly suitable for an analysis of historical changes in natural populations, since there has been little modification of these economically almost worthless areas as a result of human interference.

A correlation of evidence from cytology, geographical distribution, and geology, makes it possible partially to reconstruct the past history of the species. The area occupied by the diploids is geologically old (Cretaceous and Paleocene), and these plants, which on cytological evidence are the original form, are to be considered a relic population. The much larger area occupied by the tetraploids, however, is for the most part geologically young (Pleistocene), and it seems clear that the derived and more vigorous tetraploids have effected a great expansion of the range of the species by colonizing new territory as it became available for plant occupancy. The

advent of autotetraploidy must be considered an event of major importance in the evolution of the *Cuthbertia graminea* complex.

Autohexaploids ($6x=36$) appear to be of rare and sporadic occurrence in this species as only two individuals have been discovered so far. The evidence is as yet insufficient to justify a full evaluation of their significance. Two possible interpretations of the hexaploids are presented, however, and discussed briefly.

NOTES ON SOME BROWN ALGAE FROM THE MONTEREY PENINSULA, CALIFORNIA ¹

Gilbert M. Smith

FOR THE past five years the writer has been engaged in the preparation of a monograph on the marine algae of the Monterey Peninsula. This peninsula lies at the southern end of Monterey Bay, California, and includes that portion of the shore line between Monterey and the Carmel River. The present paper deals with certain taxonomic problems that have arisen in connection with the brown algae of this area. Most of these problems arise from the fact that phycologists working on marine algae of the Pacific Coast of North America have based their conclusions chiefly on herbarium specimens. Study of living plants, especially as they are found growing *in situ*, has revealed additional information contributing to an interpretation of certain of these controversial species.

In studying the marine algae of the Monterey Peninsula I have received assistance from various

¹ Received for publication May 18, 1942.

quarters. The Department of Botany at the University of California has offered every facility for studying their extensive collections of marine algae from the Pacific Coast of North America. Miss Rosalie Weikert has supplied information concerning Californian algae of the Anderson collection in the Phycological Herbarium of the New York Botanical Garden, and Dr. David H. Linder has answered numerous inquiries concerning material in the Farlow Herbarium. Professor G. J. Hollenberg has kindly prepared the Latin diagnosis for *Dictyonopsis*. My thanks are also due to the Research Committee of Stanford University for a grant which made possible the preparation of figures 5-13 by Mrs. Carl F. Janish.

ECTOCARPUS VARIABILIS (SAUNDERS) COMB. NOV.—In 1893 Rosenvinge found certain specimens of *Ectocarpus confervoides* with peculiar uniseriate reproductive organs which he interpreted as a row

of unilocular sporangia. Kuckuck (1894, p. 234), the next phycologist to mention these structures, interpreted them as abortive plurilocular sporangia. Sauvageau (1896) came to the same conclusion and

assumed that the abnormality was due to some unknown parasite. Saunders (1898, p. 155; pl. 23), apparently unaware of previously published observations, called them a uniseriate row of unilocular sporangia and held that their production in a row occurred with sufficient regularity to make it one of the characters in describing his *E. confervoides* forma *variabilis*. He states that they are "mostly on the same filament with the plurilocular sporangia, but much less common" whereas in his figures each of the filaments bears only one kind of reproductive organ. Setchell and Gardner (1925, p. 414), although recognizing Saunders' forma *variabilis* as distinct, are strongly inclined towards Sauvageau's interpretation of the uniseriate organs as abortive plurilocular organs.

E. confervoides forma *variabilis* Saunders is not uncommon on the Monterey Peninsula. It is epiphytic on several kelps growing between the 0.0 and -1.5 foot tide levels, but is usually found either on *Laminaria Andersonii* Farlow or on *Lessoniopsis littoralis* (Farlow and Setchell) Reinke. In *E. confervoides* f. *variabilis*, as found on the Monterey Peninsula, there are many erect branched filaments growing from a prostrate filamentous base. Some of the erect filaments bear uniseriate organs only, a considerably larger number bear only pluriseriate organs. Less than half a dozen filaments have been found with both uni- and pluriseriate organs.

Study of living uniseriate organs this past summer shows that the cells have protoplasts containing a few discoid chromatophores much lighter in color than those in vegetative cells (fig. 3-4). The lighter color of the chromatophores is thought to be a normal rather than a pathological condition. Many of the uniseriate organs were found to have discharged their contents through a single pore in the lateral wall (fig. 3). Here there was a complete discharge of the cell contents instead of a retention of some of the cytoplasm as described by Sauvageau. Unfortunately, actual discharge of the contents was not observed. The failure to observe the discharge cannot be ascribed to immaturity of material or to unfavorable conditions in the laboratory because pluriseriate organs in the same collections liberated swimmers in abundance.

There is both negative and positive evidence for thinking that the uniseriate organs are plurilocular in nature rather than a row of unilocular sporangia. On the negative side is the fact that examination of hundreds of living uniseriate organs failed to reveal a single instance where there was a cleavage of the protoplast. If the uniseriate fertile cells are unilocular sporangia, the failure to find cleavage stages is difficult to explain because, as is well known, cleavage stages are of frequent occurrence when unilocular sporangia are present in abundance. On the positive side the following reasons indicate that the fertile row is a plurilocular organ. (1) The number of enlarged fertile cells in a row is increased by transverse division just as in early development of a plurilocular sporangium. (2) A new fertile row may

Fig. 1-4. *Ectocarpus variabilis*.—Fig. 1. Branch with pluriseriate organs. $\times 100$.—Fig. 2. Pluriseriate organs. $\times 325$.—Fig. 3-4. Uniseriate organs. $\times 325$.

develop within an old empty one in just the same manner as a new plurilocular sporangium develops from the stalk cell of an old empty one. (3) There may be a development of aberrant reproductive organs which are partly uniseriate and partly pluriseriate. Sauvageau (1896, p. 143, fig. 4) interprets such structures as abnormal plurilocular organs. Saunders (1898, pl. 23, fig. 5) gives a figure of one of them but makes no comment concerning its nature. Several of these abnormal organs have been found on Monterey Peninsula material, and all of them were on filaments bearing uniseriate organs. This indicates that the pluriseriate portion is reversionary and that the uniseriate row is plurilocular in nature.

Although it seems quite clear that the uniseriate organs are plurilocular in nature, there is no evidence indicating whether they are gametangia or sporangia. The gametangial or sporangial nature of the pluriseriate organs is also uncertain. In the case of the latter organs, repeated attempts were made this past summer to obtain gametic union by mixing swimmers from different thalli but with negative results. However, even this is inconclusive because the alga may be heterogamous and the pluriseriate organs the male gametangia.

The regular production of two kinds of plurilocular organs by *E. confervoides* forma *variabilis* is so distinctive a character that it warrants elevation of the form to the rank of a species.

Thalli in gregarious tufts 0.5-2.0 cm. tall; epiphytic and attached by prostrate rhizoidal branches which do not penetrate the host; erect branches gradually attenuated, sparingly branched and with the branching predominately alternate; the cells up to 30 μ broad, with a length 1-3 times the breadth, and containing several short band-shaped chromatophores; plurilocular sporangia (?) of two sorts and usually borne on separate erect filaments; one type of plurilocular sporangium multiseriate, fusiform to narrowly ovoid, 10-15 cells broad in surface view, and with a pedicel of one to several cells; the other type uniseriate, with 2-15 barrel-shaped cells, and with a 1- to 3-celled pedicel; multiseriate sporangia 15-35 μ broad, 75-180 μ long, and with the cells about 2 μ broad; uniseriate sporangia 15-35 μ broad, 70-200 μ long, and with the cells 15-35 μ broad.

Type from Point Pinos, Pacific Grove, California. On the Pacific Coast of North America ranging from Puget Sound to central California (Carmel Bay). Also known from Greenland, Helgoland, and France.

THE CENTRAL CALIFORNIA SPECIES OF MACROCYSTIS.—Along the coast of central California, and

especially on the Monterey Peninsula, there are extensive beds of *Macrocystis* both in the intertidal zone and where the water is twenty to sixty feet deep. One or two other deep-water kelps along the coast, as *Nereocystis Luetkeana* (Mert.) Post. and Rupr., may have occasional stray individuals growing in the intertidal zone, but in the case of *Macrocystis* the intertidal individuals are so numerous and grow in such extensive stands that they cannot be considered stragglers from deeper water. At localities where deep-water beds of *Macrocystis* grow directly off shore from intertidal beds the interval between the two is barren of *Macrocystis* or contains only a few stray individuals. Examples of this on the Monterey Peninsula are to be found at Mussel Point and at Pebble Beach. Here the beds of intertidal plants end rather abruptly at the -0.5 foot tide level and the depth of water on the shore side of deep-water beds is approximately twenty feet.

In their treatise on the brown algae of the Pacific Coast of North America, Setchell and Gardner (1925) consider the intertidal and deep-water plants distinct species primarily distinguishable from each other by structure of the holdfast. *M. integrifolia* Bory, the shore species, is described as having a prostrate, dichotomously branched, flattened, rhizome-like holdfast with haptera arising along the lateral margins. *M. pyrifera* (L.) C. A. Agardh, the deep-water species, is described as having a large massive holdfast with a large number of dichotomously branched haptera. Later, as a result of intensive study of holdfasts, Setchell (1932) comes to the conclusion that there are no fundamental differences between deep-water and intertidal specimens as found between Sitka (Alaska) and Point Conception (central California). He holds that *M. integrifolia* is the only species along this long stretch of coast line. He also thinks that all *Macrocystis* from Point Conception southward to where it disappears from the North American algal flora near Magdala Bay in Baja California (Mexico) is *M. pyrifera*.

Since the Monterey Peninsula lies within the range where Setchell thinks that all individuals should be referred to *M. integrifolia*, special attention has been given to the question of differences between deep-water and intertidal specimens. More than twenty separate beds of intertidal plants have been studied on the Monterey Peninsula, and in every one of them the plants were found to have prostrate rhizomatous holdfasts; never the massive conical holdfast so frequently found on specimens of *Macrocystis* taken from deep water. The holdfasts of local intertidal plants are similar to those figured by Setchell and Gardner (1925, pl. 62) rather than to those figured by Howe (1914, pl. 19).

Intertidal plants usually grow where they are continually swept by the surf, whereas deep-water plants grow in relatively quiet water. From this it might be argued that the characteristic differences between holdfasts of the two are due to environmental factors. To test this possibility intertidal plants were collected at Pebble Beach and at Cypress

Fig. 5-8, $\times \frac{1}{2}$.—Fig. 5-6. Branch tip and holdfast of *Macrocystis integrifolia*.—Fig. 7-8. Terminal blade and holdfast of *Macrocystis pyrifera*.

Point. Pebble Beach borders a small land-locked cove where the water is always quiet; Cypress Point is a rocky headland against which the surf is continually pounding. Holdfasts of plants from these two markedly different habitats are essentially the same and show that the distinctive shape of the holdfast of an intertidal plant is not modified by agitation of the water.

Setchell's (1932) conclusion that there are no fundamental differences between holdfasts of intertidal and deep-water specimens of *Macrocystis* as found north of Point Conception was based in large part upon a comparison of adult plants. He was unable to make comparative studies of relatively young plants because he did not have specimens from deep water to compare with juvenile plants he had collected from the intertidal zone. During the past summer juvenile plants from the intertidal area have been compared with juvenile plants from deep water. The intertidal plants were collected at Mussel Point. The deep-water plants were dredged from a depth of 25 to 30 feet at a submerged reef about a quarter-mile northeast of the municipal pier at Monterey. Some of the intact deep-water plants were attached to pieces of rock broken from the reef by the dredge; others were torn from the reef by the dredge.

Little need be said concerning holdfasts of juvenile intertidal plants, since these have been fully described and adequately illustrated by Setchell (1932). As he has shown, the basal portion of the stipe becomes decumbent, distinctly flattened, and has development of haptera restricted to the two lateral margins of the flattened rhizome-like portion (fig. 6). Deep-water plants at a corresponding stage of development have an entirely different holdfast. Here the basal portion of the stipe is erect (never decumbent), and cylindrical or very slightly compressed. The haptera develop on all sides of the base of a stipe (fig. 8), instead of distichously as in intertidal plants. Holdfasts of juvenile deep-water plants are quite similar to those figured by Skottsberg (1907, fig. 98, 105-109) for juvenile plants of *M. pyrifera* as found in the Antarctic. When Monterey Peninsula deep-water plants become older there is a development of additional, radially disposed, haptera above those already formed, and production of additional haptera continues at successively higher levels until they are formed above the first forking of a stipe. Holdfasts of local deep-water plants in which haptera are being produced above the first dichotomy of a stipe bearing a strong resemblance to Setchell's (1932, pls. 40-42) illustrations of holdfasts of plants dredged at a depth of 16 to 20 fathoms near San Diego in southern California.

The blades borne at regular intervals along the stipe vary so greatly in length, breadth, dentation, bullation of the lamina, and in shape of the basal pneumatocyst, that phycologists have not utilized blade characters in distinguishing species. However, there are constant differences between terminal blades of intertidal and deep-water Monterey Peninsula plants. As is well known, the terminal blade of

Macrocystis produces new blades by splitting asymmetrically in the basal meristematic region where it joins the stipe. In the case of an intertidal plant the blade terminating a well-developed stipe is narrowly falcate, has a length five to fifteen times the breadth, and rarely has more than six young blades in progressive stages of development (fig. 5). On the other hand, terminal blades of the off-shore plant are broadly falcate, rarely have a length more than five times the breadth, and usually have ten to twenty young blades in successive stages of development (fig. 7). A similar difference is to be found in published figures of terminal blades of *Macrocystis*. Illustrations of intertidal plants from Chile (Howe, 1914, pls. 22-23) and from twenty miles south of San Francisco, California, (Setchell, 1932, pl. 34-35) show the narrow falcate terminal blades characteristic of intertidal plants on the Monterey Peninsula. The terminal blades of *M. pyrifera* as figured by Hooker (1847, pl. 171, fig. A), by Harvey (1862, pl. 202), and by Skottsberg (1907, fig. 110, 112) are of the broadly falcate type and with a considerable number of young blades incompletely cut away from the terminal blade.

The value of these terminal blade characters as a means of distinguishing between littoral and sublittoral plants was tested by requesting a colleague to make two random collections of terminal blades; one from the intertidal bed at Mussel Point, the other from a deep water bed a short distance out from Mussel Point. He was asked to put an identification tag on each blade and then to mix the two collections. The writer then segregated the mixed collection into two groups, one assumed to have been collected in the intertidal region, the other from deep water. When the results were verified by checking the numbered identification tags it was found that the source of every one of the fifty or more blades had been determined correctly. There is one point that should be noted in connection with this striking demonstration of differences between terminal blades of plants from the two habitats. In the case of the deep-water plant my colleague who collected the material worked from a rowboat and gathered terminal blades floating horizontally at or just beneath the water's surface. Thus the only terminal blades gathered by the collector were those on well-developed stipes with a length of 5 m. or more. The results might not have been so conclusive if juvenile deep-water plants had been available, since their terminal blades are somewhat narrower than those of mature plants.

There is also a constant difference between the length of local intertidal and deep-water plants. The intertidal plant is generally but 3-5 m. long, the deep-water plant frequently has a length of 15-20 m. The greatest length thus far found for Monterey Peninsula specimens of the deep-water plant is 26 m., a length considerably below the maximum of 47.5 m. recorded by Frye, Rigg and Crandall (1915) for plants found elsewhere along the coast of California. The question as to whether these constant

differences in size are due to specific differences or to environmental factors cannot be answered with certainty. In several other marine algae of the local

flora, specimens collected from the sublittoral region are regularly larger than those from the intertidal region. *Nereocystis Luetkeana* is a striking ex-

Fig. 9-13. *Dictyoneuropsis reticulata*.—Fig. 9, 11-13, $\times \frac{1}{4}$.—Fig. 10, $\times \frac{1}{2}$.—Fig. 9. Mature plant.—Fig. 10. Young plant.—Fig. 11. Beginning of longitudinal splitting of midrib.—Fig. 12-13. Stages in formation of new half-blades.

ample of this. Here the stipe is 1–2 m. long if the alga is growing in the intertidal zone, but it is up to 35 m. long if the alga is growing in deep water. The experimental demonstration (Hurd, 1916) that depth of submergence is the primary factor affecting length of stipe in *Nereocystis* indicates that differences in length between intertidal and deep-water plants in *Macrocystis* may be due to environmental factors.

Study of *Macrocystis* as found on the Monterey Peninsula shows that there are constant differences between holdfasts and terminal blades of intertidal and deep-water plants, and that these differences are not due to environmental factors. All of the evidence is in favor of the 1925 opinion of Setchell and Gardner where the intertidal and deep-water plants are considered distinct species.

DICTYONEUROPSIS GEN. NOV.—In 1895 Saunders described *Costaria reticulata*, from material collected near Pacific Grove, California. He first found fragments of blades cast ashore on the beach; later he dredged additional fragments from a depth of fifty feet and complete plants from a depth of eight to fifteen feet. Saunders separated *C. reticulata* from other species of *Costaria* because of the single longitudinal rib. The year following Setchell (1896, pp. 46–48), after studying an authentic specimen sent him by Saunders and specimens furnished by C. L. Anderson, came to the conclusion that the alga is a *Dictyoneurum* and merely a form of *D. californicum* Ruprecht, the single species of that genus. Setchell emphasized the fact that certain of Anderson's specimens had a dichotomously branched stipe with each dichotomy terminating in a single blade. From this he assumed that blades of *C. reticulata* split longitudinally in the same manner as those of *D. californicum*. He also laid great stress on the fact that juvenile blades of *D. californicum* have a differentiated axial strip resembling the midrib of *C. reticulata*. Setchell and Gardner (1925, p. 622), after studying the above-mentioned specimens and additional ones from Mrs. J. M. Weeks of Pacific Grove, unreservedly stated that Saunders had described juvenile blades of *D. californicum*.

This past summer *C. reticulata* was rediscovered growing at a depth of twenty to thirty feet near Point Aulon, Pacific Grove; and at a depth of twenty-five to thirty feet on a submerged reef about a quarter-mile northeast of the municipal pier at Monterey. The material dredged at these two localities consisted of a hundred or more fragmentary blades and thirteen intact plants with holdfasts. The latter ranged from very young plants 1.5 cm. tall to adult plants 95 cm. in height. Blades on certain of the intact plants were in various stages of splitting from base to apex and they confirm the correctness of Setchell's inference that the alga multiplies vegetatively in the same manner as *Dictyoneurum*. These plants show that splitting begins in the basal portion of the midrib of a blade (fig. 11), and then extends vertically upward to the blade apex and vertically downward through the erect portion of the

stipe. The two half-blades, each with a half of the original midrib at one side, become widely divergent soon after splitting is completed. Divergence of the two halves of a blade is accompanied by a regeneration of a new half-blade along the recently divided midrib. Regeneration of a new half-blade begins at the base of a midrib (fig. 12) and gradually extends upward (fig. 13). The fact that more than half of the hundred or more fragmentary blades brought up by the dredge had an asymmetrical midrib similar to that figured by Saunders (1895, pl. 7, fig. 1) indicates that complete regeneration of a new half-blade takes a long time.

Setchell's conclusion that Saunders' alga is more closely related to *Dictyoneurum* than to *Costaria* is undebatable. On the other hand, his conclusion that it is identical with *Dictyoneurum californicum* seems unjustified. One of his major arguments for considering the two algae identical is the fact that juvenile blades of *D. californicum* frequently have an axial longitudinal strip closely resembling the midrib of *C. reticulata*. But, as Setchell has already noted (1896, p. 47), there is always more or less reticulation of the pseudo-midrib of *D. californicum*. On the other hand, Saunders states that there are never reticulations on the midrib of *C. reticulata* and the blades collected this past summer confirm his statement. This is clearly evident on living blades. It is not so evident on blades of herbarium specimens because drying of bullations of a midrib make it seem to be reticulate. Setchell and Gardner (1925, p. 622) hold that Saunders found a midrib because he collected primary blades. The fact that every one of the hundred or more blades collected this past summer had a midrib indicates very clearly that all blades of *C. reticulata* have a midrib. Setchell was unable to corroborate Saunders' statement that the midrib portion of *C. reticulata* is about double the thickness of other parts of a blade. Measurements of a few blades dredged from the vicinity of Point Aulon showed the midrib to be 250–350 μ in thickness as against a thickness of 150–190 μ in portions lateral to the midrib.

In addition to the midrib there are several other characters distinguishing *C. reticulata* from *D. californicum*. The interspaces between reticulations in mature blades of the former are 8–30 mm. wide; those of the latter are 5–15 mm. The arrangement of reticulations is also different in the two. In *C. reticulata* the reticulations lie in an irregularly distributed pattern; in *D. californicum* the more or less rectangular reticulations so coincide with one another that there are longitudinal ridges throughout the length of a blade.

Mature blades of the two are similar to the extent that they are approximately the same breadth throughout, but the two differ markedly in shape of the basal portion. The base of a blade of *C. reticulata* is broadly rounded or even cordate; that of *D. californicum* (cf. Setchell and Gardner, 1925, pl. 70) is more or less cuneate. Differences between blade margins of the two are not constant, but blades of

C. reticulata never have the small spine-like projections which are so frequently present in *D. californicum*. There are also differences in size. Mature blades of *C. reticulata* are up to 95 cm. long, with a maximum breadth of 15–25 cm. Those of *D. californicum*, as found on the Monterey Peninsula, are up to 65 cm. long and 4–8 cm. broad.

Holdfasts of the two algae also differ in several respects. The rhizome portion of the stipe of *C. reticulata* is 4–6 mm. broad and 1 mm. in thickness; that of *D. californicum* is 6–15 mm. broad and frequently 2–3 mm. in thickness. Both algae have the haptera restricted to lateral margins of the dichotomously branched rhizomes, but the haptera themselves are different. In *C. reticulata* the haptera are three to five times dichotomous and 25–30 mm. long; on the other alga they are usually but once or twice dichotomous and 8–12 mm. long. *D. californicum* frequently has 50 to 100 blades as a result of eight to ten successive dichotomous splittings at the base of a thallus. Sufficient data are not at hand to state unreservedly that *C. reticulata* forms a smaller number of blades, but in the few intact plants collected last summer there were never more than three successive dichotomous splittings and a resultant formation of eight blades.

The foregoing discussion has shown that Saunders' alga is not a *Costaria*, and that it is a species distinct from *Dictyoneurum californicum*. If the only differences between Saunders' alga and *D. californicum* were in size, shape, and reticulation of blades, and in form and dimensions of rhizome and haptera, one would undoubtedly place *C. reticulata* as a second species of *Dictyoneurum*. The stumbling block is the lack of a midrib in blades of *Dictyoneurum*. In the case of certain other Laminariales found along the Pacific coast of North America, the presence of a differentiated axial strip through the blade has been deemed sufficient justification for recognition of new genera. One example of this is seen in Setchell's (1901, p. 123) differentiation of *Pleuraphycus* from *Laminaria*; another example is Reinke's (1903, p. 25) segregation of *Lessoniopsis* from *Lessonia*. Since "*Costaria reticulata*" seems to bear a similar relationship to *Dictyoneurum* the best solution of the problem seems to be to make it the type of a new genus. An even more important argument for considering *C. reticulata* generically distinct from *Dictyoneurum* is the clean-cut manner in which a new half-blade is regenerated along the exposed margin of a recently divided blade. There is a possibility that increase in breadth of a recently divided blade of *D. californicum* is also unilateral, but there are no coordinating points on the blade to prove that this is the case.

Dictyoneuropsis gen. nov.—Thalli perennial, at first with an unbranched prostrate stipe whose distal end bends upward and terminates in a single sublinear costate blade; decumbent portion of stipe flattened and with haptera along the lateral margins, the blade and erect portion of stipe later splitting longitudinally to form a forked stipe with each

arm terminating in a blade; blades dividing longitudinally through the midrib and regenerating new half-blades from the midrib; surfaces of blades with a coarse reticulum of narrow ridges except along the midrib; unilocular sporangia in irregularly shaped sori on both flattened surfaces of the blade, the sori at times covering the midrib. Gametophytes unknown.

Thalli perennes, primum cum stipo prostrato sine ramis, cuius terminus distalis sursum curvat et in lamina singula et sublineari et costata terminat; parte prostrata stiporum complanata et cum hapteris in marginibus lateralibus; lamina et parte erecta stipi recentius longitudinaliter diffidente et stipum furcatum faciente, quaque furca in lamina terminante; laminis per costam longitudinaliter transdividentibus, semilamina nova secundum costam regenerata; superficiebus laminarum reticulum crassum. Fastigiorum angustiorum praeter secundum costam habentibus; sporangium unilocularibus soris irregulares in utroque superficie laminarum formantibus; soris interdum costam vestientibus; plantis sexualibus ignotis.

Dictyoneuropsis reticulata (Saunders) comb. nov. (fig. 9–13).

Costaria reticulata Saunders 1895, p. 58, pl. 7.

Thalli up to 95 cm. tall; prostrate portion of stipe up to three times dichotomous; the dichotomies 4–6 mm. broad, 1 mm. in thickness; with haptera along the lateral margins, the haptera three to five times dichotomous and 25–30 mm. long; mature blades linear, slightly narrowed at upper end, broadly rounded at base; reticulation of blade restricted to portions lateral to midrib, but entire blade at times bullate; blades up to 90 cm. long, with a maximum breadth of blade 15–25 cm., midrib 1.5–3.5 cm. broad.

Growing in the sublittoral zone and at a depth of eight to fifty feet.

Type locality "Monterey Bay near Pacific Grove, Cal." Type specimen in Farlow Herbarium, Harvard University.

Also known from Point Aulon, Pacific Grove; and from one-fourth mile northeast of the municipal pier, Monterey, California.

SUMMARY

In *Ectocarpus variabilis* (Saunders) comb. nov. the uniseriate row of large fertile cells is to be interpreted as a plurilocular organ rather than as a row of unilocular sporangia.

Deep-water and intertidal plants of *Macrocytis* as found northward from Point Conception, California, have been variously considered two distinct species (*M. pyrifera* and *M. integrifolia*) and a single species (*M. integrifolia*). Comparison of holdfasts and of terminal blades of the two shows that they should be considered two species.

Costaria reticulata Saunders is made the type of a new genus, *Dictyoneuropsis*. This genus multiplies vegetatively in the same manner as *Dictyoneurum* but differs in the manner of development subsequent

to longitudinal splitting of a blade. The presence of a midrib is another reason for considering it distinct from *Dictyonereum*.

STUDIES IN THE GENUS SCIRPUS L. V. NOTES ON THE SECTION ACTAEOGETON REICH.¹

Alan A. Beetle

THE SECTION Actaeogeton Reich. of the genus *Scirpus* (Cyperaceae) falls into the subgenus *Aphylloides* Beetle (1940), being related to the sections *Schoenoplectus* Palla (*S. americanus* and its allies) and *Lacustres* Clarke (*S. lacustris* and its allies). It is easily distinguishable from both of these by the possession of black or gray-brown achenes which are marked with horizontal ridges. Only two species and two varieties out of the fifteen species and three varieties comprising the section Actaeogeton occur in North America, all the others being confined to the Old World.

In the preparation of this paper the section has been studied as a whole. The key includes all species that the material available seemed to justify. Notes on species that are not North American are included only where a nomenclatural change was necessary for the proper annotation of herbarium specimens.

In the preparation of this paper material in the herbaria of the following institutions has been consulted: Gray Herbarium (G), Harvard University; University of California, Berkeley (UC); New York Botanical Garden; University of West Virginia; California Academy of Sciences; Dudley Herbarium, Stanford University; Jessup Herbarium, Dartmouth College; Missouri Botanical Garden (MO), St. Louis; Rocky Mountain Herbarium, University of Wyoming; Field Museum of Natural History, Chicago; and the author's personal collection. In the interest of brevity the source of the specimens except in the case of types, will not be further specified.

¹ Received for publication May 19, 1942.

TAXONOMIC TREATMENT.—Section Actaeogeton Reichenbach, *Icones Florae Germanicae et Helveticae* 40. 1846. Annual or rarely perennial herbs; culms triangular or often very obscurely angled, green, smooth; sheaths usually bladeless or nearly so; outer involucre bract appearing as a continuation of the culm, green, smooth, glabrous; bristles present or absent; stamens 3; style 2- or 3-fid; achene marked by horizontal ridges, dark-gray brown or black, trigonous or lenticular, apiculate. (Type species: *Scirpus mucronatus* L.)

KEY TO THE SPECIES

Plants perennial

At least some spikelets rayed

Involucre bract short and inconspicuous, 1-3 cm. long

1. *S. brachyceras*

Involucre bract long, appearing as a continuation of the culm, 7-9 cm. long.....2. *S. inclinatus*

All spikelets sessile

Culms often 5 mm. thick at base

Involucre bract short, rarely up to 7 cm. long; bristles present.....3. *S. mucronatus*

Involucre bract long, never less than 15 cm. in length; bristles absent.....4. *S. articulatus*

Culms slender, seldom over 2 mm. thick at base

6. *S. erectus*

Plants annual

Involucre bract solitary

Achene lenticular or slightly plano-convex

Scales appressed at maturity

Spikelets 1-5; achenes olive brown

Spikelets paired.....7. *S. erectus* var. *wallichii*

Spikelets not consistently paired.....6. *S. erectus*

Spikelets many; achenes black.....9. *S. bucharicus*

Scales spreading at maturity.....13. *S. vohemarensis*

- Achene sharply trigonous
 Achene obscurely roughened
 Involucral bract strictly erect, $\frac{1}{2}$ to $\frac{2}{3}$ length of plant.....5. *S. fistulosus*
 Involucral bract often divergent or incurved, not more than $\frac{1}{4}$ length of plant
 Culms rigid, yellow-green, spikelets 1-many; upper sheaths bladeless
 11. *S. smithii* var. *williamsii*
 Culms flaccid, dull green; spikelets 1-3; upper sheaths blade-bearing.....10. *S. smithii*
 Achene prominently horizontally ridged
 Scales of spikelets spreading at maturity
 12. *S. roylei* ✓
 Scales of spikelets appressed at maturity
 Involucral bract 1-3 dm. long.....8. *S. schoofii*
 Involucral bract up to 1 dm. long
 14. *S. supinus* ✓
 Secondary involucral bract present
 Sheaths blade-bearing
 Some spikelets rayed.....15. *S. saximontanus*
 All spikelets sessile.....14. *S. supinus*
 Sheaths bladeless
 Achene dull gray-brown.....16. *S. reductus*
 Achene black
 Achene obscurely ridged, mostly not apiculate
 17. *S. uninodis* ✓
 Achene prominently ridged, apiculate
 18. *S. uninodis* var. *hallii*

1. *SCIRPUS BRACHY CERAS* Hochst. ex A. Rich. Tent. Fl. Abyss. 2: 496. 1847-51. Africa.
2. *SCIRPUS INCLINATUS* Aschers. & Schweinf. ex Boiss. Fl. Orient. 5: 381. 1884. Africa.

This species has usually been referred to as *Scirpus corymbosus* Roth, Nov. Pl. Sp. 28. 1821 which is based on *Isolepis corymbosa* Roth, ex R. & S. Veg. Syst. 2: 110. 1817. There are, however, two earlier, validly published homonyms, not only that of Linnaeus (1756, Cent. Pl. 2: 7) which refers to a species of *Rhynchospora* but also that of Forskal (1775, Fl. Aegypt. Arab. 14) which is a synonym of *Scirpus maritimus* L. *Scirpus inclinatus* is here considered the first available name.

3. *SCIRPUS MUCRONATUS* L. Sp. Pl. 1: 50. 1753. Of wide distribution in the Old World.

Scirpus mucronatus is absent from the Americas. The report of it by Britton (1888) was based on the erroneous identification of exceptionally large specimens of *S. smithii* var. *williamsii*. This same conclusion was reached by Long (1918), and agreed to by Britton, as indicated by correspondence in the Herbarium of the New York Botanical Garden.

4. *SCIRPUS ARTICULATUS* L. Sp. Pl. 1: 47. 1753. Southern Asia and Australia.
5. *SCIRPUS FISTULOSUS* Forsk. Fl. Aegypt. Arab. 14. 1775. Africa.
6. *SCIRPUS ERECTUS* Poir. in Lam. Encyc. Meth. Bot. 6: 761. 1804. Asia and the Hawaiian Islands.
7. *SCIRPUS ERECTUS* var. *wallichii* (Wight) Beetle comb. nov. China and India. *Scirpus wallichii* Nees ex Wight, Contr. Bot. Ind. 112. 1834.

This entity was well characterized by Wight whose description emphasized its important characteristics: "involucro erecto monophyllo longo tetra-

gonis spiculis subgeminis squamis ovatis acutis margine albo-membranaceis" Here, as in *S. erectus*, the style has been observed to be either 2- or 3-fid in the same spikelet. Although the variety is readily separable from *S. erectus*, its achenes are identical. Since speciation has been indicated by distinct achenes in all other cases in this section the varietal status is employed for this entity.

8. *SCIRPUS schoofii* Beetle sp. nov.

Herba caespitosa, radicibus fibrosis; culmus 3-7 dm. altus, erectus, viridis, compresso-angulatus vel teres, basi vaginatus, vaginis superioribus laminis mucronatis 1-2 cm. longis praeditis; involucrum recte apicale 1-3 dm. longum; spicae sessiles, 8-20, 7-10 mm. longae, 3 mm. latae, rubiginosae, squamae fertiles 3 mm. longae, 1.5 mm. latae, mucronatae; setae aut 6 aut saepe nullae; stylus trifidus; achenium 2 mm. longum, 1 mm. latum, triquetrum, mucronulatum, nigrum, transverse rugosulum. *Scirpo erecto* valde affinis.

Fibrous rooted annual; culms 3-7 dm. high, erect, green, slender, very obscurely angled or terete; sheathed at the base, the upper sheaths bearing rudimentary blades 1-2 cm. long; involucral bract single, strictly erect, 1-3 dm. long, slightly dilated at the base; spikelets sessile, 8-20, ovate-acute, 7-10 mm. long, 3 mm. broad, reddish-brown; sterile outer scale present; fertile scales 3 mm. long, 1.5 mm. broad, mucronate-tipped, bristles present or absent; stigma 3-fid; achene 2 mm. long, 1 mm. broad, trigonous, strongly marked with horizontal ridges, mucronate, black.

Type from China, Yunnan, *E. E. Maire* 6706 (UC).

Named for Howard William Schoof.

9. *SCIRPUS BUCHARICUS* Roshev. ex Komarov. Fl. U. R. S. S. 3: 55 (570). 1935. Asia.
10. *SCIRPUS SMITHII* Gray, Man. Bot. N. U. S. ed. 5. 563. 1867.

Scirpus smithii var. *levisetus* Fassett, Rhodora 23: 42. 1921.

Cespitose annual; culms 1-2 dm. high, erect or sometimes prostrate spreading, dull green, slender, terete or angled, sheathed at the base, upper sheaths bearing blades up to 1 dm. long; involucral bract single, up to 1 dm. long, erect or usually curved over the spikelets; spikelets usually 1-3, ovate-acute, sessile, 4-8 mm. long, 3 mm. broad; scales 3 mm. long, smooth, green, slightly mucronate-tipped; bristles absent or 2-6, equaling or exceeding the achene; style 2-fid; achene 2 mm. long, 1.5 mm. broad, shiny black, obscurely horizontally ridged, plano-convex or obscurely trigonous, apiculate.

Type from New Jersey, "shore of the Delaware below Redbank, opposite mouth of the Schuylkill, July, 1865," *C. E. Smith* (G).

QUEBEC: *Fernald* 2514. MAINE: *Fassett* 26 (type of *Scirpus smithii* var. *levisetus*). NEW HAMPSHIRE: *Pease* 19253. VERMONT: *E. & C. E. Faxon* in 1881. MASSACHUSETTS: *Weatherby* in 1911. RHODE ISLAND: *E. & C. E. Faxon* in 1880. CONNECTICUT: *Bissell* in 1910.

NEW YORK: *Haberer 1181*. PENNSYLVANIA: *Fogg 5328*. VIRGINIA: *Shull 214*.

The specimens here treated as *Scirpus smithii* form a kind of trap very frequently met in the Cyperaceae, one that catches a too literal taxonomist. Such closely allied species as *S. articulatus* and *S. erectus* may be distinguished from the closely related *S. supinus* with its sharply trigonous achene. Such characters as these suddenly become jumbled with great inconsistency in specimens of *S. smithii*, where either trigonous or lenticular achenes may be found either with or without bristles. Even the style may be inconsistently 2- or 3-fid within the same spikelet. Hence, the above characters can only serve to separate isolated specimens within this group. The more consistent characters of the obscurely roughened seed coat, growth habit, and vegetative scale and sheath shape must be relied on to define specific limits. Here again judgment must be exercised for a more unstable condition could hardly be singled out than the triangular as opposed to terete culms emphasized in Gray's Manual, ed. 7.

No entities more difficult of separation have been encountered than in the *S. debilis* Pursh-*S. smithii* complex. In the study of this group, after adopting as usual the view that a species is guilty until proven innocent, it was found that the proposed subdivisions of *S. smithii* failed to warrant independent taxonomic status. Apparently *S. smithii* is no more than an aquatic extreme of *S. debilis*. Very frequently in Cyperaceae the juvenile stages exhibit features which become lost in fully mature plants. The first sheaths formed, for example, may have long linear blades whereas the later sheaths are bladeless. From observations of sedges growing under various environmental conditions, it is suggested that plants growing in excess of water will longer retain juvenile features, e.g., blade-bearing sheaths. Typical *S. smithii* never has more than three spikelets and always has an erect but slightly incurved involucre bract. Furthermore, there is a correlation between the two characters. All specimens of *S. debilis* with three or fewer spikelets have an erect involucre bract, but those with four or more spikelets have a reflexed bract, which appears to be merely a mechanical forcing back due to the position of the fourth spikelet. *Scirpus smithii* has a more terete culm, a duller green cast, a slightly longer involucre bract, somewhat more flaccid culms, a more compressed achene that matures slightly earlier, scales more readily deciduous, and smaller spikelets than *S. debilis*. Of these characters no one seems constant, and many intermediate conditions exist. The characters are, however, clustered together in a definite pattern which allows the marking off of one side of the variation pattern as *S. debilis*, the other as *S. smithii*, and leaves the middle a no-man's land. This would seem to be an excellent series for the study of species origin. *S. smithii* suggests an incipient species, a slowly specializing complex diverging from typical *S. debilis*.

Inasmuch as *S. smithii* and *S. debilis* intergrade morphologically it is possible to draw the line between them at more than one point. A somewhat narrower interpretation of *S. smithii* than has generally been applied has been adopted here because it gives that species a more readily characterized distribution. This change of interpretation includes a change in relation for *S. smithii* var. *setosus*, it now falling in the synonymy of the *debilis* complex. *S. smithii* var. *levisetus* Fassett, characterized as having "bristles 2-6, barbless or rarely subscabrous," differs in no important respect from the type of *S. smithii*.

11. *SCIRPUS smithii* var. *williamsii* (Fernald)
Beetle comb. nov.

Scirpus debilis Pursh, Fl. Am. Sept. 1: 55. 1814, not Lam., Tabl. Encyc. Meth. 1: 141. 1791.

Scirpus debilis var. *williamsii* Fern. Rhodora 3: 252. 1901.

Scirpus smithii var. *setosus* Fern. op. cit. 1901.

Like *Scirpus smithii* but usually more robust; culms up to 6 dm. tall, bright green; the involucre bract often strongly reflexed; spikelets 1-12, bristles absent, or as many as six, occasionally strongly barbed; achene somewhat more strongly trigonous.

Type from Massachusetts, sandy shore of Massapoag Lake, Sharon, September 7, 1901, E. F. Williams and M. L. Fernald (G).

MAINE: *Fernald* in 1894. NEW HAMPSHIRE: *Wheeler* in 1904. VERMONT: *Eggleston & Jones 1726*. MASSACHUSETTS: *Fernald 16372*. RHODE ISLAND: *Reynolds 621*. CONNECTICUT: *Woodward* in 1910. NEW YORK: *Svenson 4695*. NEW JERSEY: *Woolman 128*. PENNSYLVANIA: *Bartram 1133*. MARYLAND: *Blake 8900*. DISTRICT OF COLUMBIA: *Bebb 10*. VIRGINIA: *Fernald & Long 10970*. WEST VIRGINIA: *Greenman 69*. NORTH CAROLINA: *Wiegand & Manning 634*. SOUTH CAROLINA: *Clausen & Trapido 3669*. GEORGIA: *Small* in 1893. OHIO: *Moseley* in 1896. KENTUCKY: *Svenson 4419b*. TENNESSEE: *Svenson 6867*. ALABAMA: *Vasey* in 1878. MICHIGAN: *Hanes 3695*. INDIANA: *Deam 53494*. ILLINOIS: *Mead* in 1845 (type of *Scirpus smithii* var. *setosus*). WISCONSIN: *Fassett & McLaughlin 12196*. MINNESOTA: *Grant 3294*.

If *Scirpus smithii* is considered to be specifically distinct from *S. debilis* of Pursh the latter will have to receive a new name because it has an earlier homonym.

12. *SCIRPUS roylei* (Nees in Wight) Beetle comb. nov. India.

Isolepis roylei Nees in Wight, Contr. Bot. Ind. 107. 1834.

Scirpus roylei is commonly referred to as *Scirpus quinquefarius* (Buch.-Ham. ex Wallich Cat. 121. 1828). The latter name was originally published as a *nomen nudum*, however, and seems not to have been validated before 1869-70 (Boeckler in Linnaea 36: 701), and almost certainly not before Wight validly published for Nees both *Isolepis*

roylei and *I. lupulinus* in 1834. *Isolepis roylei* is first in order. A new combination of the second name (*Scirpus lupulinus*, Roshev. ex Komarov, Fl. U. R. S. S. 3: 53. 1935) was recently made but it is a later homonym of *Scirpus lupulinus* Spreng. (Fl. Hal., Mant. 30. 1811). It, therefore, appears necessary to make a combination on *Isolepis roylei* and to treat this species as *Scirpus roylei* (Nees in Wight) Beetle.

13. *SCIRPUS VOHEMARENSIS* Cherm. Bull. Soc. Bot. France 68: 423. 1921. Madagascar.

14. *SCIRPUS SUPINUS* L. Sp. Pl. 1: 49. 1753. Europe.

15. *SCIRPUS SAXIMONTANUS* Fern. Rhodora 3: 251. 1901.

Fibrous rooted annual; culms 1–3.5 dm. high, erect, green, terete or obscurely angled, sheathed at the base, the upper sheaths often bearing blades 3–12 cm. long; outer involucre bract 5–10 cm. long, erect or incurved; second involucre bract below the spikelets, to 3 cm. long; spikelets 2 to many, both sessile and rayed; scales with hyaline margins, fimbriate, 3.5 mm. long, 3 mm. broad, the green midrib excurrent; bristles absent; stigma 3-fid; achene trigonous, dark gray-brown, prominently horizontally ridged, apiculate, 2 mm. long, 1 mm. broad.

Type from Colorado, Weld County, Greeley, E. L. Greene, September 20, 1872 (G).

OHIO: Pickaway Co., Bartley & Pontius in 1936.

SOUTH DAKOTA: Brown Co., Thorner in 1892; Bangor, Thorner in 1892, Griffiths in 1895. NEBRASKA: Kennedy, Bates in 1892; Holt Co., Tolstead 41432; Perkins Co., Tolstead 41426; Fillmore Co., Tolstead 41425; Franklin Co., Tolstead 41424, 41428, 41429; Kearney Co., Tolstead 41430. KANSAS: Rooks Co., Bartholomew in 1889. TEXAS: C. Wright; Cibola, Lindheimer; Cameron Co., Runyon 2660; Hildalgo Co., Clover 867 & 897; Bexar Co., Neally 90, Metz in 1931. COLORADO: Weld Co., bank of La Poudre, Greene in 1872. MEXICO: Lower California, Comodo Viejo, Brandegee in 1888; San Luis Potosi, Schaffner in 1877.

16. *SCIRPUS REDUCTUS* Cherm. Bull. Soc. Bot. Fr. 68: 423. 1921. Africa.

17. *SCIRPUS UNINODIS* (Delile) Boiss. Fl. Orient. 5: 380. 1884. Eurasia.

18. *SCIRPUS uninodis* var. *hallii* (Gray) Beetle comb. nov.

Scirpus hallii Gray, Addenda, Man. ed. 2. 1863.

Scirpus supinus var. *hallii* Gray, Man. Bot.

N. U. S. ed. 5, 563. 1867.

Fibrous rooted annual; culms tufted, strictly erect, up to 4 dm. high, 1–1.5 mm. thick, very obscurely triangular or terete, green, flexuous, soft,

sheathed at the base, the sheaths green, prominently mucronate tipped; reduced spikelets consisting of a single flower enclosed in a sheath often found at base of culms; outer involucre bract 3–12 cm. long, strictly erect, smooth, a second 0.5–1 cm. long, often present below the spikelets; spikelets 1-many, sessile or short-rayed, 3–15 mm. long, ovate-acute, green drying to a pale straw brown, scales 3 mm. long, keeled, mucronate tipped, appressed at maturity; bristles present or absent; style 2-fid; achene 1.5 mm. long, 1 mm. broad, plano-convex, black, apiculate, strongly marked with horizontal ridges.

Type from Missouri, St. Louis, September, 1845. G. Engelmann (G).

MASSACHUSETTS: W. Boott in 1876; Pl. Exsicc. Gray. 143. ILLINOIS: Menard Co., Athens, E. Hall in 1861. FLORIDA: Curtis 3118, Harper 38. GEORGIA: Harper 1203. TEXAS: F. Lindheimer in 1847–48.

The North American material differs from the Eurasian only in having slightly longer spikelets, and more strongly ridged and more prominently beaked achenes. That Gray recognized the close similarity of *Scirpus uninodis* and *S. uninodis* var. *hallii* is indicated by the following note in his handwriting on a sheet of the former in the Gray Herbarium: "has solitary flower in axil!—my *S. supinus hallii*—having a basal flower!"

SUMMARY

For the section Actaeogeton of *Scirpus* (Cyperaceae) fifteen species and three varieties are recognized. Distributions, descriptions, and complete synonymy are given for North American entities only. *Scirpus schoofi* from China is described as new.

DEVELOPMENT OF THE GAMETOPHYTES AND FERTILIZATION IN CAMASSIA¹

Frank H. Smith

THERE HAVE been two brief descriptions of the development of the megagametophyte of *Camassia*. Leffingwell (1930) reported what is now known as the *Adoxa*-type of megagametophyte development for *C. quamash* (Pursh) Greene. Fagerlind (1941) corrected this interpretation in a short paper describing the normal-type of development for this and two unidentified species of *Camassia*. In neither case was there any investigation of the microgametophyte or fertilization. *Camassia* provides unusually favorable material for the study of both male and female gametophytes and fertilization and has been so used in this laboratory for some time. This paper was prepared, then, with two purposes in mind: first, to give more extensive descriptions of the development of the gametophytes, especially the later development of the megagametophyte, and of the fertilization processes than are now available; and second, to recommend the use of *Camassia* in the classroom to demonstrate the development of the Angiosperm megagametophyte. In connection with the latter aim, an attempt is made to indicate the approximate rate of development of the flowers in relation to that of the gametophytes, and the time at which material should be collected for given stages.

The lily has been used almost universally in general botany laboratories to demonstrate megagametophyte development, probably because of the ease of obtaining and manipulating the material. It was known from the first that *Lilium* did not show the normal-type of development, but the original interpretation could be given to beginning students without too much difficulty or confusion. Following the appearance of the paper by Cooper (1935), however, it was recognized that the difficulties associated with the use of *Lilium* in the general laboratory were greater than had been supposed. Some attempts have been made to replace lily with some species showing the normal-type of development, such as certain of the composites, but these have not been favorably received. If a species is to be suitable for mass production of slides to show development of the megagametophyte, numerous flowers in various stages should be readily available; a fairly large number of ovules, properly oriented, should be present in each ovary; and no great difficulties should appear in fixing and staining the material. *Camassia* meets all these requirements. Bulbs may be obtained from almost any nursery; the flowers are borne in a raceme, the number varying up to thirty or more; and cross sections of the ovary give median sections of most of the ovules.

MATERIAL AND METHODS.—*Camassia Leichtlinii* (Baker) Wats. is widely distributed in the lowlands throughout the Pacific Coast states. It differs from

C. quamash in that it is usually larger, has regular flowers and perianth segments which twist about the ovary as they wither, shortly after fertilization occurs. Both species are rather widely cultivated. The two species are very similar with regard to the development of the gametophytes and fertilization. For this investigation only material of *C. Leichtlinii* is considered. This was collected, usually at weekly intervals, from plants growing in the field. Of the various fixing reagents used, Karpechenko's modification of Navashin's solution gave by far the best results for all stages. Small ovaries were fixed intact but the larger ones had their tips removed to expose the ovules. A low vacuum was used at times, but the only advantage seemed to be that it aided in infiltration with paraffin by removing most of the air from the locules. Night temperatures were fairly low during the period in which the material was collected. When ovaries were fixed in the early afternoon, there were comparatively frequent division figures in all stages. After the material was immersed overnight in the fixing solution, it was washed in running water for two hours. Dehydration and infiltration were accomplished by using a much shortened tertiary butyl alcohol schedule. After washing, the material was placed in 15 per cent ethyl alcohol for fifteen minutes, 30 per cent alcohol for thirty minutes, 50 per cent alcohol for one hour, one-half absolute alcohol and one-half Shell tertiary butyl alcohol for one hour, Shell tertiary butyl alcohol for two hours, and in three-fourths Shell tertiary butyl alcohol and one-fourth xylol for two hours. Paraffin chips were added to this mixture, and the unstoppered vials were placed in the paraffin oven for four hours. The material was then passed through two changes of a mixture of one-half Tissuemat and one-half 53° paraffin at five- to ten-hour intervals. This same mixture of Tissuemat and paraffin was also used as the embedding medium. Longer periods may be used as a matter of convenience.

Sections to show the reduction divisions and development of the megagametophyte as far as the two-nucleate stage were cut at 10 microns. Sections to show the stages from the four-nucleate condition to the early seven-celled gametophyte were cut at 12–14 microns, and the mature megagametophyte was cut at 16–18 microns. To follow the development of the male gametes in the pollen tube during their passage down the style, longitudinal sections were cut at 8 microns.

Of the staining procedures tried, the most desirable from the standpoint of results and ease of manipulation was safranin and aniline blue. The slides were stained in 1 per cent aqueous safranin for about twelve hours, rinsed in water, then in 95 per cent alcohol containing 0.5 gram of picric acid per 100 cc. for five to ten seconds. Each slide was then flooded twice, quickly, with 95 per cent alcohol containing three to four drops of ammonia per 100

cc., rinsed in fresh 95 per cent alcohol and then flooded with 1 per cent aniline blue in 95 per cent alcohol. The length of time in aniline blue is not critical. Thirty seconds to one minute was the time generally used. The stain was then rinsed off quickly with absolute alcohol and the aniline blue differentiated with clove oil. With a little practice, undesirable slides may be eliminated at this point but this must be done rather quickly, before too much blue is removed by the clove oil. The slides were then passed through three changes of xylol over a period of one hour and mounted in gum dammar. Material showing fertilization stages must be passed more slowly through the 95 per cent alcohols to remove more of the safranin than is desirable for other stages.

DEVELOPMENT OF THE MEGAGAMETOPHYTE.—A single archesporial cell is evident in the young ovule before the integuments have started to form. It may be distinguished from the surrounding cells by its larger nucleus and densely granular cytoplasm. In later stages it becomes somewhat larger than the surrounding cells of the nucellus. A single parietal cell is soon cut off, which divides, usually antichinally, very soon after it is formed (fig. 1). The inner cell enlarges rapidly, increasing mostly in length, and functions as the megaspore mother cell. Soon the nucleus enters the prophase of the first reduction division. By the time the nucleus of the megaspore mother cell is in the leptotene condition (fig. 2), the parietal cells are dividing or have divided perichinally to form four cells. In most cases no additional divisions occur in these cells. The inner integument is fairly well developed as a collar of meristematic cells around the nucellus approximately at the level of the inner end of the megaspore mother cell. The outer integument is just beginning to appear at the base of the inner integument.

The megaspore mother cell continues to elongate throughout the first reduction division. At diakinesis there are evident fifteen pairs of chromosomes (fig. 3) showing quite a wide range in size. The outer integument is just beginning to close over the base of the inner integument at this time. The chromosomes are regularly arranged at the equatorial plate during the first reduction division (fig. 4). The range in size of the chromosomes is even more evident here. Following completion of nuclear division the cell is divided, usually unequally, by a cell plate. The cell toward the chalazal end of the ovule is considerably larger than the other (fig. 5) and may develop a somewhat thicker wall. The second reduction divisions are also normal, though division of the outer cell may be slightly slower than that of the inner one (fig. 8). By this time the outer integument has enlarged so that it extends forward to about halfway over the inner integument. In most cases the spindles of the second reduction divisions are so arranged that their long axes coincide with the long axis of the original mother cell, and a linear tetrad (fig. 7) is formed. In perhaps one-fourth of the ovules, however, the spindle in the cell nearer the

micropyle is at right angles to the other and a T-tetrad results (fig. 8). When the outer cell, of the two formed after the first division, divides later than the inner one, the daughter cells produced are the first ones to show signs of degeneration. Usually all three outer cells eventually begin to degenerate and the chalazal megaspore, which up to now has been uniformly granular, becomes somewhat vacuolate (fig. 9). Rarely both the inner megaspores may germinate to produce two embryo sacs which may be superimposed at maturity or arranged side by side.

The reduction divisions in the megaspore mother cells occur in the older flowers of racemes which are just emerging from the ground. The first and second reduction divisions in the microspore mother cells occur while the megaspore mother cells are in the early prophase of the first reduction division. The first and second nuclear divisions in the megaspore may be found in the older flowers of racemes of which the flower stalk alone is approximately two to three inches high.

The small vacuoles which appear in the megaspore as it enlarges soon merge and usually form a single large vacuole in the micropylar end of the cell, while the nucleus moves nearer the chalazal end. At times, however, a second and smaller vacuole may be formed in the chalazal end of the megaspore (fig. 10). The degenerating megaspores are much flattened and densely staining at this time. The inner integument now completely encloses the nucellus, and the outer integument encloses the inner up to approximately the level of the megaspore. The first nuclear division in the megaspore (fig. 11) occurs at approximately the same time as the division of the microspore. The spindle is located near the chalazal end of the cell, but one of the daughter nuclei soon moves through the cytoplasm down one side of the cell to the micropylar end. Thus, at the two-nucleate stage the cell has typically a single large vacuole in the center and a nucleus near either end (fig. 12). These nuclei then divide simultaneously (fig. 13) with apparently no consistency as to orientation of the spindles. The outer integument at this time extends up to about the tip of the nucellus and the degenerating megaspores have practically disappeared. The parietal cells start disintegration at about the time of the first nuclear division in the megaspore and at this stage have also practically disappeared. Fagerlind (1941) reported the disintegration of the parietal cells as occurring somewhat earlier in *C. quamash*. With the disappearance of the three outer megaspores and the parietal cells, the developing megagametophyte becomes sub-epidermal.

Following the completion of the second nuclear division, some of the spindle fibers persist as very delicate strands between the daughter nuclei (fig. 14). Fibers which remain in the cytoplasm after completion of the next to last nuclear division in the megagametophyte have been described in *Lilium* by Cooper (1935) and also in other species by various workers. These persistent fibers later bring about

cell plate formation to aid in the production of the seven-celled megagametophyte.

The ovules in a single ovary, except for a few at the end nearest the style, develop at approximately the same rate up to the four-nucleate stage. There may then follow a period of growth, variable in extent, before the nuclei divide to form the eight-nucleate megagametophyte. Because of this variation there is also considerable variation in the time of formation and in the size of the seven-celled gametophyte. It may be larger or smaller than the average, as its size depends on the length of the growth period during the four-nucleate condition. In general, however, the older flowers of racemes with the flower stalk approximately six inches high will give mostly stages from the early four-nucleate condition to early seven-celled megagametophytes. These older flowers are about 12 mm. long. A complete range of stages may be found at times in a single ovary.

During the third nuclear division in the megagametophyte (fig. 16), the fibers persisting from the second division are present but they are quite delicate and rather difficult to demonstrate. There seems to be no single arrangement of the spindles at the chalazal end of the cell that can be considered as typical. The spindle nearest the chalazal end is usually arranged approximately parallel with the long axis of the megagametophyte, but the other spindle may be oriented in any direction. At the micropylar end the two spindles are usually at approximately right angles to each other, in either of the positions shown in figures 15 and 16. Cell division is accomplished by cell plate formation essentially as in *Lilium* (Cooper, 1935). Cell plates are first formed across the spindles of the third nuclear division (fig. 15). Additional fibers appear in the region of the persistent fibers from the second divisions, and these soon also form typical cell plates. Once initiated, cell division is apparently completed in a short time.

Shortly after cell division is completed, the polar nucleus from the micropylar end of the primary endosperm cell moves up to the vicinity of the chalazal polar nucleus (fig. 17). At the same time there seems to be some increase in the amount of cytoplasm in this cell. A large strand of dense cytoplasm appears which extends from the vicinity of the immature egg apparatus to the polar nuclei. This strand usually passes directly through the large central vacuole, but it may also appear as a dense ridge of cytoplasm along one wall of the cell. The cells at the ends of the young gametophyte are regular in form and are frequently isodiametric or approximately so.

There then follows a rapid enlargement of the primary endosperm cell. The antipodal cells become denser and somewhat reduced in size. The three micropylar cells also become slightly denser and appear to be flattened by pressure exerted by the enlarging endosperm cell (fig. 18). The polar nuclei usually fuse at about this time. Though in some instances the fusion may be delayed for some time, in

every case observed the polar nuclei fuse before fertilization occurs. There is little change in the appearance of the polar nuclei during fusion. The reticulum in each nucleus remains as fine threads and stains lightly throughout the process. The nuclei become flattened on the sides of contact (fig. 18); the nuclear membranes disappear in this region; and the resultant nucleus becomes rounded. The nucleoli also appear to fuse and the fusion nucleus always has a single very large nucleolus (fig. 29). Numerous stages showing this enlargement of the primary endosperm cell and the fusion of the polar nuclei were obtained from the older flowers of racemes with flower stalks approximately sixteen inches high. These flowers were about 22–24 mm. in length. The flower stalks and flowers develop rapidly at this time. There was an interval of only three days between these collections and those made when the flower stalks were only six to seven inches high.

After the primary endosperm cell has enlarged to almost mature size, the egg apparatus begins to grow. The egg enlarges more rapidly than the synergids. The egg nucleus is always in the upper portion of the egg and a large vacuole develops in the lower portion (fig. 19). The synergids also enlarge at one end to form small, cone-shaped cells, each with a projection from the enlarged upper end surrounded by a circular depression (fig. 19). As these cells continue to enlarge, they push into space originally occupied by the primary endosperm cell which, at the same time, apparently sends folds downward to enclose partially both the egg and the synergids. The reticulum of each synergid nucleus begins to lose its chromaticity and becomes rather indistinct. Differentiation of the filiform apparatus begins at about this time and apparently results from the formation of elongate vacuoles in the micropylar end of the cell. The cell wall covering this end of the synergid also stains lightly with safranin at this time. The small projection from the center of the upper end of the synergid then enlarges; the nucleus moves up into this projection; and vacuoles appear in the cytoplasm above the nucleus (fig. 20). The egg is still growing more rapidly than the synergids. Enlargement is due primarily to the increase in size of its single large vacuole. Figure 20 represents a section made at approximately right angles to the plane of figure 19 so that taken together the figures show the relative positions of the egg, synergids and enclosing folds of the primary endosperm cell. The filiform apparatus becomes more distinct and the cell wall at the upper limits of the filiform apparatus begins to appear granular and to stain more heavily with safranin. The granular material in the cell wall forms a complete circle around each synergid at the level indicated. A small ledge is still evident at this time at about the middle of each synergid against which the folds of the primary endosperm cell lie rather closely.

The vacuoles in the upper end of each of the synergids then coalesce to form a single large vacuole (fig. 21), and the synergids enlarge rapidly to mature

size. At maturity the ledges seen at the middle of each synergid in figure 20 are no longer evident. At the upper ends of the synergids the walls are extremely thin and delicate, while along the sides the walls are comparatively heavy. At about the upper limits of the filiform apparatus the walls now stain rather heavily with safranin and particularly so with crystal violet. Figure 21 represents the condition of the micropylar end of the megagametophyte at the time the flower opens.

Up to the four-nucleate or early eight-nucleate stages of the megagametophyte, growth in width occurs mostly at the lower or micropylar end. During the later stages of enlargement of the primary endosperm cell, however, the upper end increases much more in diameter than the lower so that at maturity the megagametophyte is top-shaped. The antipodal cells, already showing signs of degeneration, are crowded into a small chalazal cavity above the center of the primary endosperm cell. Figure 29 illustrates a portion of the chalazal end of the gametophyte at the time of fusion of a male nucleus with the fused polar nuclei. With the exception of the presence of the male nucleus, this figure indicates the approximate condition of the antipodal cells and the fusion nucleus at the time the flower opens. During the final stages of development, the strand of dense cytoplasm extending from the micropylar end of the endosperm cell to the fusion nucleus may increase in thickness, while at the same time there is an apparent decrease in the thickness of the layer cytoplasm around the sides of the cell.

THE MALE GAMETOPHYTE.—Microsporogenesis is typical in all respects and is not illustrated. Both first and second reduction divisions in the microspore mother cell occur while the megaspore mother cell is in the early prophase of the first reduction division. After cell division is completed, there follows a long period in which each microspore increases in size and the spore walls are formed. During this period a large vacuole is present surrounded by a relatively small amount of cytoplasm. The young microspores are not well preserved with Navashin's solution. As the microspore nucleus prepares to divide, however, there is a considerable increase in the amount of contained cytoplasm, and the vacuole becomes much smaller. At this time the microspore and all stages of nuclear and cell division are well fixed with Navashin's solution. While there is some variation in the time of division of various microspores, even in the same anther sac, in general the microspore divides at approximately the time of the division of the megaspore nucleus; that is, in the older flowers when the flower stalk is about two to three inches high. The spindle is oriented with one pole directed toward the spore wall (fig. 22). No irregularities during the division were observed, and the generative cell is cut off by cell plate formation (fig. 28). The generative cell is discus-shaped at first, but it eventually rounds up and becomes enclosed by the tube cell. Elongation of the generative cell does not occur until it enters the pollen tube.

As the pollen tube is formed, the tube nucleus usually moves out of the pollen grain first. The generative cell of necessity becomes cylindrical with rounded ends as it enters the pollen tube. The generative nucleus may already be in the early prophase of mitosis at this time. The process of division apparently takes considerable time and various stages in the process may be found in longitudinal sections of styles taken five to fifteen hours after pollination. During the late prophase the small chromosomes are well spread out over the nucleus and may be counted rather easily. A normal spindle with rather sharp poles is formed (fig. 24) with the equatorial plate extending either practically straight across the cell or at a slight angle. The chromosomes, particularly the larger ones, may be arranged parallel with the spindle. The chromosomes mass closely together during the anaphases, but in the early telophases they soon become dispersed and persist for some time as definite units (fig. 25) before forming a very coarse reticulum. A cell plate appears which results in the division of the generative cell into the two male gametes. Delimitation of the male cells by the formation of vacuoles on either side of the cell plate, as described by Johnston (1941) was not observed, but no special attention was given this phase of the process. The reticulum of the nucleus in each male cell, in contrast with that of the tube nucleus, stains heavily with safranin throughout the passage of the gametes through the pollen tube to the ovule. Nucleoli are not evident in the gametes at this time. While in the style, the male gametes are usually some distance behind the tube nucleus, which remains at the tip of the pollen tube. As the pollen tube enters the micropyle, however, the male gametes are near the tube nucleus. Just outside the ovule the male gametes may be easily observed as distinct cells (fig. 26). As reported by Leffingwell (1930) for *C. quamash*, it requires approximately eighteen hours for the pollen tubes to reach the ovules. This will vary somewhat, of course, with variations in temperature. Covering the placentae and extending to the micropylar tips of all ovules at maturity, there is a mass of apparently gelatinous material. The pollen tubes grow in or on this material but are not restricted to it. The material does not stain when the safranin-aniline blue technique is used, but it stains heavily with fast green.

FERTILIZATION.—Many stages in double fertilization were found in material collected twenty to twenty-five hours after pollination. As pointed out by Wylie (1941) for *Vallisneria*, apparently only a very short interval elapses here between the emergence of the gametes from a primary pollen tube and fertilization. The only complete male gametes observed in the megagametophyte in this study were from secondary pollen tubes. Such gametes were observed to have become more rounded after their release from the pollen tube (fig. 28). There is a very delicate cell membrane and the nucleus itself is almost spherical. The reticulum of the male gamete

in the pollen tube outside the ovule stains heavily with safranin, but upon reaching the megagametophyte, from the time of emergence from the pollen tube to the completion of fertilization, the reticulum stains only lightly with safranin but rather heavily with aniline blue.

As the pollen tube enters the megagametophyte, usually only one synergid is penetrated. This one is filled completely by the pollen tube, and the combined cells stain rather heavily with safranin. The thin membrane across the top of the synergid is ruptured and contents from the pollen tube, and probably some from the ruptured synergid, flow out across the top of the egg (fig. 27). In the earliest stage of fertilization observed, the rounded male nucleus was already inside the egg in contact with the egg nucleus. A nucleolus is not yet evident in the male nucleus at this time. The male nucleus then becomes somewhat flattened, and small lobes appear to reach out over the surface of the egg nucleus (fig. 27). Following the dissolution of the intervening membranes the two nuclei are incorporated into a single nucleus. However, the reticulum of the male nucleus is evident for some time in the zygote because of its coarser nature and greater chromaticity. This reticulum develops a small nucleolus after it is incorporated in the zygote nucleus (fig. 30). This late development of the nucleolus of the male gamete has been described by Gerassimova (1933) and others.

The second male nucleus is apparently released from its cytoplasm as the gamete enters the primary endosperm cell or very shortly thereafter. It immediately moves up the large strand of cytoplasm leading to the fused polar nuclei. It reaches the fusion nucleus only a very short time after the other male nucleus has begun to fuse with the egg nucleus. The stages in nuclear fusion are approximately the same as those in the egg except that the male nucleus usually enlarges to a somewhat greater extent before being incorporated into the primary endosperm nucleus (fig. 29). The fate of the tube nucleus and of the nucleus of the destroyed synergid was not determined.

During this time the folds of the primary endosperm cell continue to enlarge and enclose the egg apparatus more completely. After fertilization is completed, the destroyed synergid and the pollen tube lose their chromaticity and are rapidly absorbed. The uninjured synergid decreases in size, rapidly at first, because of the passage of material from the vacuole at the upper end (fig. 30). It soon disappears completely. There is a rapid accumulation of cytoplasm in the zygote, and the primary endosperm nucleus moves down near the zygote before it begins to divide. By this time the folds of the primary endosperm cell are much enlarged and almost completely enclose the zygote (fig. 30). The antipodal cells have degenerated to a considerable extent by this time and soon become entirely absorbed. Division of the primary endosperm nucleus then occurs, followed by several successive nuclear

divisions before the zygote divides. These early divisions in the endosperm occur approximately at the time when the perianth segments begin to dry and become twisted around the ovary.

SUMMARY

There are fifteen pairs of chromosomes in *Camassia Leichtlinii*. The megagametophyte follows the normal-type of development. Cell division is accomplished by cell plate formation by fibers of both the second and third nuclear divisions in the formation of the gametophyte. The polar nuclei fuse before the gametophyte is mature. The synergids are first flattened by pressure from the enlarging primary endosperm cell. They then enlarge and develop into cone-shaped cells showing a filiform apparatus in the cytoplasm. A dark-staining ring of granular material in the cell wall appears at the upper level of the filiform apparatus. The three antipodal cells degenerate soon after fertilization.

The pollen grains are two-celled. The generative cell in the pollen grain is round and enclosed by a distinct membrane. It becomes cylindrical as it enters the pollen tube and, following a typical mitosis, is divided by the formation of a cell plate. The male gametes persist as complete cells until they are discharged into the megagametophyte.

Various stages in the development of the gametophytes were correlated with the external development of the flower stalk and flowers.

The pollen tubes reach the ovules approximately eighteen hours after pollination, and fertilization occurs two to five hours later. Only one synergid is penetrated by the pollen tube as it enters the megagametophyte. Secondary pollen tubes were also observed. Double fertilization occurs at approximately the same time in a given megagametophyte. A nucleolus is not developed by the reticulum of the male gamete until nuclear fusion is completed.

It is recommended that *Camassia* be used in the classroom instead of *Lilium* to demonstrate development of the Angiosperm megagametophyte.

SPIRAL GROWTH AND REVERSAL OF SPIRALING IN PHYCOMYCES, AND THEIR BEARING ON PRIMARY WALL STRUCTURE¹

Edward S. Castle

MOST INVESTIGATORS would agree that there is a high degree of orientation in the structure of the plant cell wall. In some measure this extends even to the structure of the tenuous, growing, primary wall of the enlarging cell. Such structural orientation is shown largely by the occurrence of cellulose in the form of microfibrils, themselves crystalline, lying in one or more preferred orientations, usually in the plane of the cell surface. Cell enlargement is accompanied by expansion or growth of the primary wall, and involves the deposition of new wall material in an oriented pattern.

What determines the characteristic form of cell growth and the pattern of its wall structure has never been clear. Plant growth hormones probably act not directly on the wall but at some prior stage in the complex process of growth. On the other hand, microscopic and X-ray investigations have been most successful in dealing with secondary wall structures where the cell is already beyond the stage of active enlargement. Thus, although the primary wall is of the greatest physiological interest, we have the least satisfactory knowledge of its fine structure and mode of growth.

There is, however, an additional line of evidence that can be brought to bear on primary wall structure. In some types of cell the orientation of the growth process can be studied. Where this has been possible, growth has been found to be highly oriented, and it appears that such growth co-exists with oriented structure of the growing wall. Oriented growth may be defined as active enlargement along a preferred axis or axes. For example, many cylindrical cells have attained their shape primarily by elongation, and might as a first approximation be said to possess growth oriented along their long axis. Tissue cells, however, may have been passively oriented in their growth by mechanical influences. Hence, it is not possible to consider from this point of view such interesting cell types as the cambial elements or the much-studied cells of the *Avena* coleoptile.

The occurrence of oriented growth in cells which are at all free to determine their own shapes clearly indicates the existence of a directional property in the structure of the growing wall. Some authors have regarded the preferred axis of cell enlargement as directly determined by the existing wall structure (Bonner, 1935; van Iterson, 1937; Diehl, *et al.*, 1939; Ziegenspek, 1939, 1941). Broadly interpreted, this view should permit inferences as to orientation of structure from studies of oriented primary wall growth.

It is regrettable that we lack adequate information about the orientation of growth in cells whose primary wall structure is best known, such as the

cotton fiber (Anderson and Kerr, 1938; Berkley, 1939; Hock, Ramsay, and Harris, 1941). Almost the only available data relate to the growth of the sporangiophore of *Phycomyces*, where a spirally oriented form of growth occurs. The mature cylindrical sporangiophore elongates by growth which is restricted to an apical zone proximal to the terminal sporangium. The axis along which elongation takes place is not parallel to the long axis of the cell, but makes an angle with it which may be as much as 30°. Hence, the sporangium and the terminal region of the cell are rotated about the long axis during growth, and the cylindrical sporangiophore forms a spirally-wound wall structure (Oort, 1931; Oort and Roelofsen, 1932; Castle, 1937, 1938).

Spiral growth is by no means confined to *Phycomyces*. It exists in the related fungus *Mucor mucedo*,² and according to Astbury and Preston (1940) occurs in *Cladophora* where, significantly, spiral wall structure also is found. It is likely that suitable growth studies will reveal that the incidence of spiral growth is more general than has been supposed. Heyn (1939) has listed some five attempted explanations of spiral growth, as many as two "theories" being ascribed to the present writer. It is evident that where there is so much theory there must be a dearth of fact, and the work described in this paper was undertaken primarily to give a more complete picture of the facts of spiral growth in *Phycomyces*.

MATERIAL AND METHODS.—The "plus" strain of *Phycomyces blakesleeana* was grown in small vials on autoclaved white flour paste, which supports luxuriant growth. Isolated sporangiophores were obtained by clipping away all but one of those present in a culture. In order that growth might be followed in localized regions, individual markers were attached to the sporangium or to the sporangiophore with a micromanipulator. Single spores of *Lycopodium* were found to make excellent markers. They were easily attached by a touch of the micromanipulator needle and showed up well in photographic records of growth.

In general, automatic photographic recording was employed, using a special camera magnifying ten times. The culture vessel with a suitably marked sporangiophore rested in a moist, glass-walled chamber with a constant dim light overhead to ensure vertical growth. The camera was placed in front of the chamber and was driven parallel to the chamber at a slow, constant rate by a lead screw turned by a synchronous motor acting through a train of gears. Periodically, the sporangiophore was brightly illuminated with red light from one side and automatically photographed, the travel of the camera being briefly in-

¹ Received for publication June 18, 1942.

Fig. 1. Diagram of developmental stages of the sporangiophore of *Phycomyces*. Regions in which growth is taking place are stippled. Note apical growth of tubular sporangiophore in stage 1. When the sporangium appears as a terminal swelling, growth in length shortly ceases, and growth during stage 2 becomes confined to sporangial enlargement. In stage 4a elongation sets in again, and the sub-sporangial growing zone lengthens as the growth rate accelerates. The rotary component of spiral growth is not shown in these diagrams. In stage 1 the axis of growth is directed sinistrally, in stages 2-3 growth is unoriented, in stage 4a dextral spiraling occurs, and in stage 4b sinistral spiraling takes place (see text).

interrupted during the exposure. The red light was outside of the phototropic range, and was cooled by passage through a water filter. Because the object was brightly illuminated against a dark background, a series of exposures could be obtained on a single plate. Figures 2, 3 and 4 are contact prints of such records, slightly reduced in reproduction. A modified form of the same apparatus permitted taking serial pictures of a cell from above instead of from the side, although not automatically. Figures 6 and 7 are enlargements of such records, and constitute the most direct way of demonstrating the rotary component of growth.

STAGES OF GROWTH.—Four developmental stages in the growth of the sporangiophore of *Phycomyces* were described by Errera (1884). In stage 1 the sporangiophore grows upward from the mycelium

as a simple pointed tube with apical growth; in stage 2 the tip of the cell begins to swell to form the sporangium, and elongation ceases; stage 3 is a period of two to three hours during which no further swelling of the sporangium occurs and elongation is at a standstill; in stage 4 elongation begins again and continues for many hours. During this last stage the previously yellow sporangium rapidly becomes brown and then black in color as the spores ripen. This is the "grand period" of growth which has been widely used for growth and tropistic studies.

Graser (1919) was unable clearly to separate stages 2 and 3, but Grehn (1932) believed the distinction to be valid. In the present paper stages will be designated as by Errera, although 2 and 3 will for convenience be treated together. If stage 3 is a

Fig. 2-7. Photographic records of growth.—Fig. 2. Growth of sporangiophore and process of sporangium formation, stages 1 and 2. Note characteristic refractive droplets exuded by stage 1 sporangiophore. Time lapse interval fifteen minutes. $\times 9$.—Fig. 3. Swelling of sporangium, stage 2, with markers attached to pole of sporangium. Rotation absent. Time lapse interval fifteen minutes. $\times 9$.—Fig. 4. separate entity, it is set off from stage 2 only by the complete cessation of sporangial enlargement. As will be seen below (fig. 1), stage 4 can properly be divided into two substages, 4a and 4b, on the basis of their different modes of spiral growth.

RESULTS.—It is convenient to describe the observations on growth in terms of the various stages described above and illustrated in figure 1.

Stage 1.—Figure 2 shows on the left a series of pictures at fifteen-minute intervals of the young, stage 1 sporangiophore. The total height of the cell attained before swelling of the tip begins (stage 2) varies greatly with the culture conditions. In the small vials commonly used, stage 1 cells rarely exceed 3 to 5 cm. in length. Cultured on the same medium in liter flasks, however, the cells usually grow to lengths of 10 cm. or more before sporangium formation begins. In the figure, a marker attached to the left side of the cell not far below the tip appears as a small white spot. In successive pictures this spot can be seen to move upward with decreasing velocity, finally becoming stationary as it passes out of the growth zone. The length of the growth zone is thus given by the distance from the tip of the cell to the marker when it just ceases further upward movement. At this point it will be noted that a number of other white spots appear in the photograph around the marker. These are visible farther down the cell in the earlier pictures, and extend above it in later ones, giving the dotted appearance to the margins of the cell in figure 2. The spots are reflections from droplets formed on the outside of the cell, and are characteristic of stage 1 sporangiophores. They first appear just below the lower limit of the growth zone, and rapidly increase in size. Their presence is an additional indication of the length of the growing zone, which extends from just above the first-formed, uppermost droplets to the tip of the cell. Doubtless these droplets are comparable to those which are exuded so conspicuously by the sporangiophores of *Pilobolus*. It is striking that droplets are never formed on the wall during any of the later stages of growth of *Phycomyces*, not even in stage 4 (cf. fig. 4 and 5).

Although consistent spiral growth of stage 1 cells has not previously been found (Castle, 1936), re-examination shows that these cells do show spiral growth. If pains are taken to attach markers to the extreme tip, they are found to progress slowly around the cell as well as to be carried upward in the usual way by growth occurring below them. There is, therefore, a rotary as well as a longitudinal component of growth. That rotation is not due to passive torsion of the whole cell can be seen by

simultaneous observation of markers attached below the growth zone.

Figure 6, *a* to *n*, shows photographs taken of a stage 1 cell from above, with markers attached on opposite sides of the growing tip. In these pictures the cell grows directly toward the camera, and in successive pictures taken at fifteen-minute intervals the markers can be seen to move clockwise around the cell's long axis. (This axis is perpendicular to the plane of the paper.) Of the fifteen stage 1 cells tested, nearly all showed this rotary component of growth, though not all to the same degree. Only two of the fifteen seemed to have no rotary component. Rotation in this direction corresponds to growth occurring along a steep left-hand spiral which runs around the cell like the thread on a left-handed screw.

Even when markers are attached at the extreme tip of the cell, the maximum rotation which has been observed is about 90° (cf. fig. 6 *a*, 6 *n*). By contrast, markers attached in the growth zone of stage 4 cells often make one and one-half to two complete revolutions about the axis (Castle, 1937). Thus in stage 1 markers pass out of the growth zone relatively fast, due in part to the fact that the growth zone is on the average only about half as long in stage 1 (1 mm.) as in stage 4 (1.5 to 2 mm.). This fact has made it difficult to determine the angle of inclination of the spiral, but in a few favorable cases it can be roughly estimated as about 10° . This angle represents the deviation of the spiral axis of growth from the long axis of the cell. It is noteworthy that qualitatively the direction of the spiral is left-handed (sinistral) and in this respect similar to the characteristic sinistral growth in stage 4.

Stages 2 and 3.—Stage 2 begins with the swelling of the tip of the sporangiophore and continues through maturation of the sporangium. As the tip swells, elongation below it falls off and finally ceases, so that all growth becomes confined to sporangial enlargement. During this enlargement a mass of yellow, carotenoid-rich protoplasm passes up the sporangiophore and into the sporangium, and the initially hyaline swelling becomes brightly pigmented. The taking over of growth by the sporangium is diagrammed in figure 1, and shown in actual records in figures 2 and 3.

Attachment of markers to the sporangium shows that there is no rotary component of growth during sporangial enlargement. The markers on top of the sporangium in figure 3 separate slightly as the circumference of the sporangium increases, but show no trace of rotation. The chief point of interest, then, is the absence of oriented growth during stages 2

to face of sporangium and of sporangiophore. Rotation begins as dextral, then reverses and becomes sinistral. Time lapse interval fifteen minutes. $\times 9$.—Fig. 5. Stages 4a and 4b as in preceding figure. Markers on face of sporangium and on side of sporangiophore. Note initial dextral rotation followed by reversal. Time lapse interval fifteen minutes. $\times 19$.—Fig. 6. Stage 1 sporangiophore photographed from above, with markers attached on opposite sides of tip. Growth is toward the camera. Clockwise rotation of markers indicates sinistral spiral growth. Markers separate as growing apex increases in diameter. Time lapse interval ten minutes. $\times 75$.—Fig. 7. Stage 4b sporangium photographed from above, with markers on equator of sporangium. Growth is toward the camera. Rotation is clockwise, indicating sinistral spiral growth. Time lapse interval five minutes. $\times 23$. The stationary white spot on the left side of each sporangium in figures 3, 4, 5 and 7 is a highlight, and remains in a fixed position in spite of rotation.

and 3, although they are both preceded and followed by stages having oriented growth. As mentioned above, stage 3 appears to be only a brief prolongation of stage 2 in which sporangial enlargement has ceased. It is difficult to determine whether this is really a separate stage because the increments in diameter of the sporangium have by now become small.

Stage 4.—With the sporangium completed, elongation of the sporangiophore again commences. Since this is the stage which exhibits conspicuous spiral growth, the initial period of stage 4 is of especial interest.

It was found that at the outset of renewed elongation and for a period of an hour or more, growth is again spirally oriented, but is *dextral* (right-handed) instead of sinistral. At the end of this time, the direction of rotation reverses and becomes sinistral. Normal sinistral spiral growth then remains in force for the duration of stage 4, a matter of many hours or days. This transitory period of reversed, dextral spiraling was found uniformly in the large number of cells examined, and is evidently a normal phase of growth.³ It has, therefore, been designated stage 4a to distinguish it from the sinistral phase which follows, the latter being termed stage 4b (fig. 1). The separation of these two sub-stages is based on the hitherto undetected reversal of the direction of spiraling. Throughout stage 4a and well into stage 4b the velocity of simple elongation is smoothly accelerating and appears unaffected by the reversal of the rotary component of growth (fig. 8).

Reversal is clearly shown in figures 4 and 5. Markers have been attached to the sporangia, and appear as irregularly spaced white (or dark) spots on the nearly spherical sporangia. The large white equatorial spot which appears on the left side of each sporangium is not a marker but a highlight, which naturally remains in a fixed position in spite of rotation of the sporangium.

Beginning with the first picture on the left in figure 5 and progressing to the right, the markers can be seen in the first six pictures apparently to move across the face of the sporangium until they appear silhouetted on its right margin. This motion is actually due to dextral spiral growth of the sporangiophore, stage 4a. In the eighth picture from the left,

³ It was present in cells grown at 14° as well as at 22°–25°C.

the markers have started back across the face of the sporangium, and they continue in this direction until in the twelfth picture they have disappeared on the other side. In the next picture they reappear on the right margin, and henceforth this right-to-left travel across the face of the sporangium will continue. This is the normal sinistral spiral growth of the sporangiophore, stage 4b (fig. 7).

Fig. 8-9.—Fig. 8 (above). Time course of elongation after sporangium formation. At the dotted vertical line dextral spiral growth reverses and becomes sinistral (see fig. 9).—Fig. 9 (below). Time course of rotation after sporangium formation, showing reversal of direction of spiraling.

TABLE 1. Elongation and rotation in stage 4a, with calculated initial angles of dextral spiraling in stage 4a and of sinistral spiraling in stage 4b.

Cell No.	Duration of stage 4a in hours	Elongation in stage 4a in mm.	Rotation (dextral) in stage 4a	Initial angle of dextral spiraling in stage 4a	Angle of sinistral spiraling in stage 4b
1	1.25	0.33	53°	11°	8°
2	1.25	0.38	66°	11°	7°
3	1.50	0.40	50°	7°	7°
4	1.75	0.45	84°	10°	4°
5	1.50	0.50	104°	15°	12°

On five separate records comparable to figure 5, measurements were made of the duration of dextral spiral growth and of the magnitude of its two components, elongation and rotation. These are given in the second, third, and fourth columns of table 1. Duration was measured only to the nearest quarter hour. Elongation was derived from direct measurements on the record. Rotation was calculated from changes in the position of the markers on the face of the sporangium. From table 1 it will be seen that the average duration of stage 4a is about an hour and a half at room temperature (22°–25°C.). Elongation during this time is between 0.3 and 0.5 mm., and the concomitant dextral rotation is between 50° and 100°.

Detailed data for cell No. 5 are plotted in figures 8, 9, and 10. Figure 8 shows the time course of elongation for three hours after the start of stage 4a. There is no perceptible change in the growth curve at the point where dextral spiraling reverses and becomes sinistral (vertical broken line). Figure 9 shows the corresponding course of rotation. For nearly an hour and a half the rate of rotation (dextral) is smoothly accelerating, then it begins to fall off and within half an hour sinistral rotation has become established. The further course of the curve in stage 4b will cut the baseline, which is arbitrary, and continue steeply downward, indicating continued sinistral spiraling.

More light is shed on the process of growth if the time factor is eliminated, and the rotational component plotted directly against elongation. If a fixed relation exists between the two components, we expect a linear plot the slope of which is a measure of the angle of spiral growth. The data for cell No. 5 are plotted in this manner in figure 10. Here it is seen that at the outset of stage 4a rotation keeps pace with elongation, as indicated by the linear ascending portion of the curve. This means that dextral spiraling begins at a fixed angle the moment any growth occurs. Regular spiraling at this angle continues for over an hour, then rotation begins to fall behind elongation, ceases where the curve passes through a maximum, and reversed spiraling (sinistral) then commences. The baseline in figure 10 is again arbitrary, and sinistral spiraling will normally continue throughout stage 4b. The transition period from stable dextral to sinistral spiraling, represented by the curved, upper region of the plot in figure 10, lasts about three quarters of an hour. At the end of this time, a stable angle of spiraling has been re-established, but in the opposite direction (sinistral). All five of the analyzed growth records show these same features, with minor differences in times and angles.

From simultaneous measurements of rotation and elongation it is possible to calculate α , the approximate angle of spiral growth, expressed as the deviation of the axis of growth from the long axis of the cell.

$$\tan \alpha = \frac{\pi D \theta}{360 h}$$

Fig. 10. The two components of spiral growth plotted against each other. At the outset of stage 4a, dextral spiraling begins at a fixed angle as shown by the linear ascending limb of the curve. Reversal occurs at the dotted vertical line, and shortly thereafter a stable angle of sinistral spiral growth is established.

where D = diameter of the cell, θ = rotation in degrees, and h = elongation. The linear slopes in figure 10 give the ratio θ/h , and D is measured directly. Columns 5 and 6 of table 1 give the approximate calculated values of α , both dextral and sinistral, for each of the five cells analyzed. The initial angles of dextral spiraling (column 5) are between 7° and 15°, and fall within the range normally found for sinistral spiraling (Castle, 1936). The ensuing angles of stable sinistral spiraling (column 6) tend to be somewhat smaller than the preceding dextral angles.

A number of cells were studied both at the end of stage 1 and during stage 4a to make sure that the dextral spiraling which appears immediately after sporangium formation was not previously present. All cells so studied showed normal sinistral spiraling at the very end of stage 1. During stages 2 and 3 there was no rotation of any kind, but the same cells exhibited dextral spiraling at the outset of stage 4a.

An important related point concerns the locus of renewed growth when stage 4 commences. During sporangium formation the cell wall below the sporangium shows no growth. It remains, in effect, a proximal portion of the wall of the simple stage 1 sporangiophore. The renewal of growth in stage 4 occurs precisely in this sub-sporangial region of the cell (see stippled regions in fig. 1). When this region was growing previously, its growth axis was directed sinistrally, yet in stage 4a it starts to grow again but with the axis of growth directed dextrally. Something has happened during the formation of the sporangium to cause the same cell wall to reverse its direction of spiral growth, although within about an hour it again returns to the sinistral pattern.

The initiation of growth during the early part of stage 4a was studied in detail by attaching during stage 2 a series of markers along the front or side of the sub-sporangial region which was destined to become the growing zone in the ensuing stage 4 (cf. fig. 5). When growth started, changes in the separation of these markers or in their relative positions to the right or left permitted estimation of the location of growth and of its dextral or sinistral components.

Such studies show that at the outset of stage 4a growth first begins at a point about 0.6 mm. below the sporangium. For a time the growing zone is short, then it progressively lengthens upwards toward the sporangium. Within two hours the growth zone has reached its typical length of 1.5 to 2 mm. During this time the total rate of elongation has also been increasing. While dextral growth takes place, all markers within the growing zone show displacement to the right, indicating that the entire growth zone participates in the dextral growth. As dextral growth lessens toward the end of stage 4a, the markers in the growth zone progressively lessen their dextral motion. When sinistral growth begins, all the markers in the growth zone begin to move sinistrally. From these observations it is clear that the gradual transition from dextral to sinistral spiral growth is not due to the fact that some parts of the growth zone continue to grow dextrally while others begin to grow sinistrally and gradually take over control of the orientation of growth. Rather it is that the entire growth zone contributes to the total dextral component measured at the sporangium, and then the dextral orientation within the whole growing zone gives way to a sinistral orientation within that same growth zone.

Discussion.—Study of the early stages of growth of *Phycomyces* has revealed a remarkable complexity yet consistency in its growth pattern. The chief new aspects of this pattern are as follows:

- (1) Contrary to previous belief, growth of the sporangiophore during stage 1 commonly possesses a rotational component, the axis of growth being directed sinistrally. If such sinistral growth is reflected in a helical wall structure, this has so far escaped detection (Castle, 1938). A critical reexamination of structural orientation in the primary wall of stage 1 cells is, therefore, called for.
- (2) Sporangial enlargement (stage 2) occurs as a spherical inflation of the tip of the sporangiophore. This process possesses no rotational component and appears to be a case of non-oriented growth. The factors which initiate sporangial development and the associated loss of oriented growth are unknown. Growth in this stage resembles passive inflation of an isotropic membrane, as if structural elements in the sporangial wall had no preferred orientation beyond that of lying tangentially in the surface.
- (3) When growth of the sporangiophore is established in stage 4, it immediately shows dextral spiral growth, although previously this same region of the cell had been growing sinistrally. After dextral spiral growth for somewhat more than an hour

(stage 4a), the orientation of growth reverses and becomes sinistral. Thereafter this sinistral mode of growth is maintained (stage 4b).

It would be rash to attempt to explain such an array of facts in terms of any one of the existing theories of spiral growth. Although Heyn (1939) has listed some five "theories" of spiral growth, there are in reality three basic ideas involved. First, the concept that protoplasmic streaming orients chain molecules which are being built into the wall (Pop, 1938). Second, consideration of geometrical factors in the curvature of the growing wall which influence the distribution of elastic stresses and of chain molecules or fibrils bearing these stresses (Castle, 1936). Third, the idea that growth occurs as slippage along inclined planes of weakness in a crystalline grid (Heyn, 1936, 1939). Each of these concepts is too limited alone to permit explanation of the complex nature of spiral growth in *Phycomyces*.

Evidence has accumulated that plant cell walls may consist of a number of superimposed lamellae in which the orientation of microfibrils of cellulose varies from layer to layer (Bailey, 1940; Bailey and Berkley, 1942). In particular, Astbury and Preston (1940) have described for the walls of *Valonia* and *Cladophora* a series of lamellae in which the cellulose chains in any one layer make an angle of nearly 90° with those in the layers next above and below. In the primary wall of cotton, Anderson and Kerr (1938) have shown three systems of microfibrils in a single wall thickness: two opposing systems of crossed, spirally-wound fibrils, and a third system transverse to the long axis of the cotton fiber. These findings have been confirmed by Hock, Ramsay, and Harris (1941). Preston, long an advocate of a single spiral orientation in conifer tracheids (1934, 1939a), has recently stressed the significance of the double crossed spiral pattern such as is found in *Valonia* and *Cladophora* (1939b).

Should the crossed spiral arrangement turn out to be widespread in primary walls, it would be of importance in the interpretation of growth. There is evidence that elongation of plant cells tends to take place perpendicular to the direction in which the cellulose chains principally run, if only because separation of the chains and hence growth is possible in that direction. Since this fact admits a relation between primary wall structure and growth, it can be concluded that spiral growth reflects the occurrence of spirally oriented wall structure.

If a primary wall were composed of only two spiral systems which cross, we could not foresee whether growth would occur in the direction perpendicular to one set of fibrils or to the other, or whether growth might not take place along some intermediate resultant path of least resistance. Factors governing the outcome in a cylindrical cell would certainly be: (1) the angle of inclination of each spiral system from the long axis of the cell. These angles need not be the same, as in *Cladophora* where one system is a steep, the other a low, spiral. It is interesting that Astbury and Preston report clear

evidence of spiral growth in *Cladophora*, although no measurements of its inclination were made. (2) The angle of crossing of the two systems. In *Valonia* and *Cladophora* this angle approaches 90° . In cotton it is 40° or less. (3) The relative strengths of the opposed spiral systems.

It is speculative at the moment to suggest that the reversals of spiraling which occur in *Phycomyces* are founded upon a system of crossed spirals in the primary wall. Yet the manner in which the angle of spiral growth shifts from a stable dextral to a stable sinistral angle is hard to visualize in any other terms. The facts show that in stage 1 spiral growth tends to occur along an axis inclined sinistrally from the long axis of the cell. This might indicate a structural system the predominant orientation of which is along a dextral spiral of low pitch. While the cell "rests" during sporangium formation, a sinistrally oriented structural system may be added to the wall, so that when growth begins in stage 4a its spiral component is predominantly directed perpendicular to this new structural system, i.e., dextrally. Why spiral growth shortly reverts to the fundamental stable sinistral pattern is, however, not clear.

Study of the orientation of growth brings important evidence to bear on the structure of the growing wall. Except in the cases cited above where definite crossed spiral systems have been described, primary wall structure has been variously pictured as amorphous, statistically isotropic, or at best a confused tangle of cellulose microfibrils. The complex but consistent sequence of changes in the orientation of growth of *Phycomyces* clearly shows that some-

thing imposes definite directional properties upon the process of growth. It appears most plausible that these directional properties are determined by the structure of the wall itself. Whether they are explicable in terms of oriented fibrillar systems or of as yet unknown factors remains for a closely coordinated study of growth and of structure to show.

SUMMARY

Largely by automatic photographic recording, a study was made of the rotational and elongational components of growth of the sporangiophore of *Phycomyces*. The presence of a rotational component indicates the occurrence of spirally oriented growth. Prior to sporangium formation, the simple tubular sporangiophore commonly exhibits spiral growth which is directed *sinistrally*. During swelling of the cell tip to form the sporangium, there is no rotational component and growth is temporarily unoriented. When growth of the cell in length is resumed, *dextral* spiral growth sets in at once. About an hour and a half later, dextral spiral growth regularly reverses and becomes *sinistral*. Sinistral orientation of growth is then normally maintained thereafter. This consistent sequence of changes in the orientation of growth emphasizes the existence of directional properties in the primary wall. The possibility that reversal of spiral growth is explicable in terms of a crossed spiral structure of the primary wall layers is discussed.

NOTE ON PHOTOTROPISM IN PILOBOLUS¹

Lewis H. Flint

DURING A series of lectures by Dr. A. H. R. Buller at Louisiana State University in the summer of 1941 a survey of the work on *Pilobolus*² was presented which directed attention to the highly specialized mechanism orienting the sporangia with respect to light, to the seeming importance of carotin in relation to such orientation and to the researches indicating that *Pilobolus* responded to the light of all the regions of the visible spectrum. Dr. Buller's presentation prompted the present inquiry.

That radiant energy has to be absorbed before it can become effective in stimulating a biological response is a precept of long standing known as the Grotthus law. Among green plants the phototropic response has been commonly observed to be incited by radiations of a wave-length shorter than about 5,400 Å. Absorption by carotenoids is typically negligible from 5,400 Å to 8,000 Å, so that from a physical standpoint an apparent association of these substances with phototropism is in line with the Grotthus precept. On the other hand, the reported bending of plants toward radiation of wave-lengths longer than about 5,400 Å is definitely disconcerting. With respect to *Pilobolus*, therefore, one might be tempted to suggest that either *Pilobolus* does not turn toward red light or that, if it does turn, there must be some pigment present which absorbs in the 5,400 Å to 8,000 Å range.

The light-sensitivity of *Pilobolus* has been studied by a number of investigators. The conclusions reached from the earlier researches were not in agreement and in an effort to clear up the muddled situation Parr (1918) carried out extensive studies at the University of Illinois, assisted by some members of the Physics Department. It appears to have been largely through these studies that the idea of a general sensitivity to radiations throughout the visible spectrum became favored for *Pilobolus*. The paper by Parr (1918) included a valuable survey of researches on *Pilobolus*, together with an excellent bibliography. More recently Bünning (1936-1937) carried out researches designed to appraise the valid-

ity of a proposed association between phototropism and carotenoids. In his first paper he questioned the method of Parr; yet upon adopting a preferred method he reported *Pilobolus kleinii* as sensitive to red light characterized by the wave-length range 6,500 Å to 6,900 Å. In a second paper he attempted to correlate the carotin content of *Phycomyces*, *Pilobolus*, and the *Avena* coleoptile with the degree of phototropic sensitivity of the respective involved structures. The substantial order of agreement appeared complicated by the revealed association of chlorophyll with carotin in the *Avena* coleoptile following exposure to light. In a third paper he reported failure to demonstrate with *Pilobolus* or *Phycomyces* a satisfactory agreement between the absorption curve of a specific carotenoid and the curve of phototropic response of the carotin-containing structure. With respect to green plants, his researches led him to implicate chlorophyll as associated with the phototropic response, an involvement which appeared to complicate the interpretation of phototropism in fungi.

The proposed sequence in the present series of experiments designed for a further study of the light-sensitivity of *Pilobolus* was as follows: (1) to verify the turning of *Pilobolus* to red light and (2) having verified the turning, to extract the pigment and determine the absorption characteristics within the range of visible radiation.

Before proceeding with tests involving *Pilobolus*, it seemed desirable to set up a beam of red light of measured wave-length range and intensity and to make certain that this beam incited no phototropic response in green plants. For this purpose a dark box was provided adjacent to the exit slit of a reflecting monochromator. A General Electric S-type single-coil filament lamp operated at 12 volts was the source of light. The slit widths were so adjusted as to yield a beam of radiation centered at 6,800 Å (wave-lengths ranging from 6,576 Å to 7,024 Å) with an intensity of the order of 800 ergs/cm². About 200 seeds of Italian rye grass were planted in a 400 ml. Pyrex beaker half full of moist soil. The beaker was so placed that germinating seedlings, upon reaching the top of the beaker, would extend

¹ Received for publication February 24, 1942.

² Part I of Volume VI of Dr. Buller's esteemed *Researches on Fungi* is concerned with the biology and taxonomy of *Pilobolus*.

into the horizontal beam of red light. Germination was practically 100 per cent. The growth of the seedlings in red light was uniformly upright and the plants were deep greenish orange-yellow, in contrast to the pale straw color of plants developed simultaneously in complete darkness. There was thus assured a horizontal beam of radiation that would promote chlorophyll development and yet be of such a quality as to fail to incite phototropic response.

Two types of experiments were then carried out with *Pilobolus*, one involving observations on bending or the orientation of the fruiting structures with respect to the direction of the horizontally-incident light, and the other involving observations on the disposition of discharged sporangial masses with respect to the radiation. In both types of experiments the initial procedures were the same. Dung balls obtained from a horse pasture were placed in moist chambers kept at moderate temperatures. As soon as *Pilobolus* became distinguishable, suitable individual balls were selected and removed to the experimental conditions.

In the experiments designed to provide for the observation of the bending or orientation of the fruiting structures the dung balls were suspended on fine wires over water in 400 m.l. Pyrex beakers, each wire being held to the underside of a superimposed Petri plate cover section by means of a bit of modeling clay. The covered beakers with enclosed balls were placed in the dark box in the horizontal beam of radiation.

When grown under the conditions above described and tested, the fruiting structures of the *Pilobolus*³ developed and became extended within the beam of red light, but in no instance was there any evidence of an orientation toward the horizontally-incident light source. The tests in the red light were observed after twenty-four hours, but were continued for forty-eight hours. They were repeated extensively, and in the aggregate they comprised hundreds of fruiting stalks. By way of contrast, similar tests were carried out in a beam of radiation centered at 4,600 Å, and marked orientation was observed in all fruiting structures in all tests at the end of twenty-four hours. Further tests indicated that, placed in this radiation at right angles to the beam, *Pilobolus* would become fully oriented toward the blue light source in about seventy minutes at 25°C.

In the experiments designed to provide for the observation of discharged sporangial masses, suitable dung balls were placed on moist filter paper in the center of ordinary Petri plates. An extra cover was inverted and placed beneath the plate so as to elevate the original cover and provide for suitable space to permit the discharge of the sporangial masses. The apparatus was placed in the horizontal beam, and the direction of the incoming light was indicated by an arrow marking. After seventy-two hours the plates were removed. The disposition of the sporangial masses was recorded by markings made on a

³ The material used in these studies appeared to be *Pilobolus longipes* van Tieghem.

Fig. 1. Distribution patterns of *Pilobolus* sporangia. The fruiting structures were developed in light at horizontal incidence, the direction being indicated by arrows. Each dot marks the point of impact of a sporangial missile upon the superimposed Petri plate. Above, radiation centered at 6,800 Å; below, radiation centered at 4,600 Å.

piece of clear cellophane placed over the top cover of the Petri plate. The tracings indicated that there was no tendency of the discharged sporangial masses to present an enhanced frequency of distribution in the direction of incident radiation centered at 6,800 Å. The experiments of this type were repeated extensively and in the aggregate they also comprised hundreds of fruiting stalks. By way of contrast, similar tests were carried out in a beam of radiation centered at 4,600 Å. In these tests the distribution of the sporangial masses was such as to evidence a marked orientation of fruiting structures with respect to the direction of the incident radiation. The distribution patterns obtained with 6,800 Å radiation and with 4,600 Å radiation are shown in figure 1.

It was clear that these results removed the occasion for endeavoring to extract from *Pilobolus* a pigment absorbing red light. While the results were at variance with those reported by Parr (1918) and by Bünning (1936-1937), yet in indicating phototropic light-sensitivity as restricted to the short wave-

length range of visible radiation they indirectly appeared to give emphasis to the carotenoid-phototropism association so thoroughly studied by Bünning. Continuing, however, with *Pilobolus*, devoid of chlorophyll, demonstrable as having a phototropic light-sensitivity comparable with green plants, the results might also be interpreted as somewhat at variance with the chlorophyll-carotenoid alliance proposed by Bünning. In Zscheile's (1941) review of plastid pigments the absorption curves for various carotenoids were given. These curves indicated that absorption ceased within the range of 5,000 Å to 5,400 Å, which range also covered the variation found among the results of investigations involving the upper wave length limit of the phototropic response in green plants.

SUMMARY

When continuously exposed to radiation centered at 6,800 Å with a range 6,576 Å to 7,024 Å, an inten-

sity of the order of 300 ergs/sec/cm²., and demonstrable as non-phototropic to green plants yet promoting chlorophyll development, the fruiting structures of *Pilobolus* did not become oriented with respect to the source of light and discharged their sporangia at random. These results were not in agreement with those reported by Parr and by Bünning, yet they were consistent with the Grotthus precept and the association of carotenoids with phototropism.

PRELIMINARY REPORT ON THE INTERGENERIC MATING OF THRAUSTOTHECA CLAVATA AND ACHLYA FLAGELLATA¹

S. B. Salvin

MANY SPECIES of the Saprolegniaceae combine asexual characters of two or more genera of that family. These include, for example:

(1) *Protoachlya* sp., in which the spores are diplanetic, "... on emerging ciliated, and all or some showing sluggish or less often active motion, some remaining attached in an irregular clump to the tip of the sporangium" (Coker, 1923);

(2) *Isoachlya* sp., in which the sporangia arise "either by cymose or pseudo-cymose arrangement, as in *Achlya*, or by internal proliferation as in *Saprolegnia*, both modes occurring earlier or later in the development of one and the same species, or frequently on the same main hypha" (Coker, 1923);

(3) *Achlya dubia* Coker, in which the spores emerge "as in *Achlya* or as in *Thraustotheca* in varying proportion, ... not rarely ... as in *Dictyuchus*" (Coker, 1923);

(4) *Thraustotheca primoachlya* Coker and Couch, in which the spores of the initially formed sporangia are "usually of the *Achlya* type, ... the spores discharging through an inconspicuous apical papilla or clustering at the tip," whereas the later sporangia burst "at the tip or sides, or in both places, the spores swelling out by degrees and the sporangial wall in large part disappearing" (Coker and Couch, 1924);

¹ Received for publication April 13, 1942.

Contribution from the Laboratories of Cryptogamic Botany and the Farlow Herbarium, Harvard University, No. 212.

The author expresses his gratitude to Professor W. H. Weston for his valuable suggestions and continued interest during the course of this study.

(5) *Dictyuchus achlyoides* Coker, in which sporangia of "both *Achlya* and *Dictyuchus* types" are "abundant, the *Achlya* type appearing first, the *Dictyuchus* ones later" (Coker, 1927); and

(6) *Thraustotheca bispora* (Salvin, 1942) (= *Brevilegnia bispora* Couch; cf. Couch, 1927), in which the initial sporangia resemble "the *Achlya* type, many of which, however, lack a distinct papilla of dehiscence, a considerable part of the sporangial tip giving way for the exit of the spores," and in which the later sporangia are "of the same shape and size as the early ones but [dehisce] by the swelling of the spores and consequent bursting of the sporangial wall much as in the later sporangia of *Thraustotheca primoachlya*" (Couch, 1927).

The mixed characteristics of these species may be (1) an indication of their primitiveness, *i.e.*, they contain several characters which in later evolution may become separated in different forms, or (2) the result of intergeneric matings, *i.e.*, species with different sporangial characters may have fused sexually to give rise to generations which combine the qualities of the two parents. This latter possibility has never been demonstrated experimentally, *i.e.*, no one has ever successfully brought about the fertilization of the oospheres of one species with the antheridia of another. The writer, therefore, conducted experiments to determine whether such matings may be induced between two homothallic species with declinous antheridia. Although fifty-one combinations of species were tried, only one resulted in interspecific matings (fig. 1), namely, the combination of *Achlya flagellata* and *Thraustotheca clavata*. These two species were used in the subsequent

Fig. 1. Illustration of attempted interspecific matings.

experiments because they form many oogonia and diclinous antheridia in agar media when the culture is but a few days old, and their oospheres do not develop parthenogenetically. This combination of species was especially effective, since the early formation of oogonia in *A. flagellata*, occurring less than forty-eight hours after growth had begun, induced in *T. clavata* the development of antheridial branches before that of oogonia. Thus, it was possible to trace the oogonia and the attached antheridia to their respective sources, and accurately determine their specific origin. The main difficulty was in the fact that antheridial hyphae of *A. flagellata* were formed just prior to and simultaneously with the oogonia of that species and fertilized most of the enclosed oospheres.

MATERIALS AND METHODS.—Success in the mating experiments was first attained when the two fungi were inoculated on 25 cc. standard Difco corn meal agar about 6 cm. apart and diametrically opposite one another. When the respective mycelia grew toward one another and eventually became intermingled in a narrow band approximately midway between the two points of inoculation, examination of this band usually revealed several oogonia of *A. flagellata* partially enveloped by antheridia of *T. clavata*. Under these conditions, it was a long and difficult task to determine the origin of the sexual structures and subsequently to isolate them, especially since the antheridia of *A. flagellata*, which had appeared at the time of oogonium formation, fertilized most of the *Achlya* oogonia.

Therefore, attempts were made to find an experimental arrangement in which the origin of the antheridia and the oogonia from the two mated species

could be easily established and in which mature oospores, resulting from intergeneric matings, could be easily obtained in large numbers. Although the writer tried several methods of growing these two fungi in close proximity, none showed any improvement over the original one. However, some are worthy of further elaboration, because they were partly successful and might offer suggestions for further approach to the problem. The techniques (a) of growing the organisms on half-strength Difco corn meal agar as above and (b) of inoculating each fungus on a hemp seed and then placing the resulting young mycelia adjacent to one another in 15 cc. of water did not reduce the time nor the difficulty of experimentation. Since it was believed that if the mycelium were impeded by a wall perforated by a tiny hole, a few hyphae would proceed into the area beyond, a rectangular cup of thin cellophane, containing a tiny hole in the center of each of the longitudinal walls and half-filled with nutrient or non-nutrient agar, was placed midway between the points of inoculation of the fungi. Although a few hyphae of each of the inoculants entered the cellophane cup

Fig. 2. Camera lucida drawings illustrating fertilization of an oogonium of *Achlya flagellata* by an antheridium of *Thraustotheca clavata*. $\times 300$.

through each of the perforations, these hyphae did not grow directly toward one another and bring about sexual fusion, but branched, curled, and spread about profusely, thus making the determination of the origin of the respective sexual structures even more difficult.

RESULTS AND DISCUSSION.—The writer was, therefore, driven by necessity to the long and arduous task of tracing the hyphae bearing the antheridia and oogonia to their source in order to determine accurately the point of origin of the respective sexual structures. Under these conditions, as the oogonia of *A. flagellata* developed alongside the hyphae of *T. clavata* in 25 cc. of Difco corn meal agar, antheridia of the latter species were formed and attracted to the adjacent oogonia (fig. 2, A, B). Eventually, these antheridia became attached, formed fertilization tubes, and apparently brought about fertilization, since oospores appeared shortly thereafter (fig. 2, C, D).

Although several cases of "imperfect hybridization" have been described in interspecific and intergeneric crosses in the Saprolegniaceae (Couch, 1926; Raper, 1939) and the Mucoraceae (Blakeslee, 1915), the successful mating of two separate homothallic species of the Saprolegniaceae has never been reported. The foregoing results, therefore, are the first to indicate that sexual fusion may occur between the homothallic thalli not only of two separate species but also of two separate genera.

However, until the oospores are germinated and the characteristics of the resulting generations studied, the experiments do not prove conclusively that sexual or nuclear fusion took place between the two species. When attempts were made to germinate under ordinary environmental conditions the oospores resulting from the intergeneric matings, not a single oospore, when transferred to nutrient agar, gave rise to a vegetative mycelium. Therefore, in order to stimulate this germination, oogonia containing these oospores were removed from the agar about a week after their maturation and subjected to (a) drying at room temperature for two weeks, (b) drying for

a week and heating to 100° F. for six to seven hours, and (c) drying for two to three weeks at a temperature of 5° C. Subsequently, when the treated oogonia were placed in a nutrient agar, no germination followed. This failure to germinate may be attributed to the lack of proper conditions, although there is the alternate possibility that these oospores are non-viable.

In spite of the failure to induce germination of the oospores, the significance of these intergeneric matings of two homothallic species is great. In the first place, these matings indicate that sexual fusion in nature may well occur between homothallic species of the same or different genera of the Saprolegniales. In the second place, this intergeneric fusion suggests that species with intermediate asexual characters may have originated from interspecific hybridization. Also, the sudden appearance of an atypical method of asexual reproduction in a given species may be similarly explained. In the third place, there is the indication that the modern concept of a genus in the Saprolegniaceae is possibly inadequate in that it does not take into consideration the possible mingling of characters as a result of intergeneric matings. Finally, there may well be a closer phylogenetic relationship between some of the genera of that family than is at present recognized.

SUMMARY

That many species of the Saprolegniaceae have asexual characters which are typical of or intermediate between two or more genera of that family may be the result of intergeneric matings. When attempts were made to mate species of different genera, one proved successful, namely, that between *T. clavata* and *A. flagellata*. However, the oospores resulting from this intergeneric fusion did not germinate, probably because of the lack of proper conditions therefor.

WATER UPTAKE BY EXCISED ROOT SYSTEMS OF THE TOMATO DUE TO NON-OSMOTIC FORCES¹

J. van Overbeek

THE CLASSICAL concept of water uptake into cells by means of osmosis is so universally accepted that it is often regarded more as a fact than a convenient theory. Root pressure also is often considered to be entirely osmotic in nature (Sabinin, 1925; Crafts and Broyer, 1938). However, experiments are known which make it appear as if osmosis is inadequate to explain the water uptake of cells. Ursprung and Blum's experiments (1921, 1925) seem to show that water uptake by the cells of the endodermis is possible against an osmotic gradient. Bennett-Clark and Bexon (1940) have experiments which tend to show that the "water absorbing power" of the leaf cells exceeds the osmotic pressure of the vacuole. Heyl (1933) concluded from a study in which he investigated the effect of temperature upon the rate of bleeding and the rate of backward movement of the exudate under influence of plasmolytica, that the mechanism of bleeding cannot be exclusively osmotic in nature.

The purpose of this investigation was to find out experimentally whether or not osmosis alone is capable of explaining root pressure. In order to do this, a simple basic experiment was designed by which it was possible to measure (A) the osmotic pressure of the exudate² and (B) the pressure with which water is taken up by the roots. If these two values are equal in magnitude, root pressure can be explained on the basis of osmotic pressure alone. If the pressure with which water is taken up by the roots (root pressure) is larger than the osmotic pressure of the exudate, then root pressure is due to other causes in addition to osmosis.³

The root pressure was determined as the osmotic pressure of a mannitol solution which exactly compensated the root pressure.

TECHNIQUE.—Seeds of "San Jose Canner" tomatoes were sown in sand in flats and watered with Hoagland solution. After the seedlings were six to eight weeks old, they were transferred to culture solutions with forced aeration in one of the air-conditioned greenhouses (26.5°C. and 70 per cent humidity). For constancy of temperature and other properties of these greenhouses, see Went (1942). In order to avoid "shock" reactions the experiments (with the exception of the one mentioned in fig. 3) were carried out at the same *constant conditions* as those under which the plants were grown. The in-

dividual plants were held with non-absorbent cotton in paraffined wooden lids, which were placed on one-gallon mayonnaise jars which were painted white over a black undercoat and filled with Hoagland solution (Hoagland and Arnon, 1938). In order to obtain plants rich in carbohydrates which would be capable of carrying on metabolism for a considerable time after they were decapitated, the nutrient solution was not renewed, but the water lost by transpiration was replaced by distilled water. In this way low-salt plants which are rich in carbohydrates (Hoagland and Broyer, 1936; Grossenbacher, 1938) were obtained. The pH was adjusted periodically and maintained between 5 and 6, and ferric chloride was added weekly. The Hoagland solution was renewed in a few special experiments which will be mentioned later. In the experiments mentioned in the last section, dealing with the effects of KCN, a nutrient solution suggested by Arnon and Hoagland (1940, p. 477) was employed. Exceptional root growth was obtained in this solution and the pH adjustments were not necessary. Iron citrate was given twice weekly.

After the plants had grown from four to seven weeks in the culture solution, they were cut about one to two inches above the uppermost roots. This decapitation was done about noon, because it was found that plants cut earlier in the day often did not bleed at all, even when left for a day or longer. After decapitation the plants were transferred to distilled water. In some experiments distilled water was put in the culture jars a few days before the plants were decapitated (fig. 1). The root system was put in *distilled water* because it eliminates accumulation of solutes as a complicating factor in the process of exudation; it also increases the rate of exudation over that of root systems kept in nutrient solution. In some experiments (fig. 2) the roots were kept in a full-strength Hoagland solution instead of in water. This did not influence the results, however. It only caused a slower rate of exudation and a higher osmotic pressure of the exudate. During the experiments, as well as during the growing period, forced aeration was used continuously.

The stump of the plant was attached to a thick-walled U-tube with narrow bore, by means of a small piece of rubber tubing firmly attached to the stump with string. In this manner a perfectly water-tight connection was obtained which allowed the U-tube to be interchanged conveniently for a horizontal "potometer" tube (for rate determinations). The majority of plants bled profusely, often at a rate of 2 cc. per hour. After a minimum of 2 cc. of the exudate was collected for freezing point determinations, the U-tube was replaced by a horizontal thick-walled tube (inside diameter 0.042 inches). The meniscus moved rapidly outward.

¹ Received for publication April 18, 1942.

² The nomenclature regarding osmotic quantities proposed by Meyer (1938) and Meyer and Anderson (1939) is used throughout. Therefore "osmotic pressure" of the exudate denotes "osmotic value" or "osmotic concentration" of the older literature.

³ It is assumed that the osmotic pressure of the exudate equals, or at least is not higher than, that of the contents of the vessels down in the water-absorbing region of the roots. Evidence for the correctness of this assumption is given later in the paper.

Next a concentrated mannitol solution was carefully added to the distilled water in which the roots were immersed. Mannitol is an osmotically active but otherwise a physiologically inert substance which penetrates into cells with great difficulty (Colander and Bärlund, 1933), and for this reason is to be preferred to substances such as NaCl. At a concentration just sufficient to stop the bleeding, the osmotic pressure of the mannitol solution equals the pressure with which the roots take up water (root pressure). A rapid circulation of the solution was obtained by means of forced aeration. Mannitol was added until the meniscus remained stable for five minutes. If too much mannitol was added, the meniscus moved inward, and some of the solution in the 600 cc. beaker in which the roots were immersed was poured off and replaced by water until the "compensation point" was reached. "Rebound" effects such as reported by Rosene (1941a) in onion roots were also observed in the tomato roots. These effects may be due to cortical and other cells between the xylem and outside solution coming into equilibrium with each other and their surroundings. In order to avoid errors due to such "rebound" effects a total of fifteen minutes was allowed for finding the mannitol concentration which just stopped bleeding. The method is very sensitive, and the effect of a single drop of concentrated mannitol solution added to the solution in the 600 cc. beaker may be noticed in the movement of the meniscus in the horizontal tube. The method has an advantage over methods determining the rate of bleeding in that changes in the water permeability of the root cells do not affect the root pressure determinations.

After the mannitol concentration was found which would stop water uptake by the roots, a sample of the mannitol solution was taken for *cryoscopic analysis*, the roots were rinsed and placed in fresh distilled water and some more exudate was collected. The entire procedure was repeated several times. In later experiments (fig. 1) root pressure measurements were made immediately after the plants were decapitated. In earlier experiments (fig. 3) a sample of exudate was collected before the first root pressure measurement was made. It was often possible to make five root pressure determinations and to collect four samples of exudate within seven hours after the plant was decapitated (fig. 1). The osmotic pressure of the exudate was measured cryoscopically with a small Beckman apparatus with which samples as small as 2 cc. could be analyzed. In doing the

Fig. 1-2. Root pressure compared with osmotic pressure of the exudate.—Fig. 1. The pressure with which an excised root system takes up water (vertical lines R) exceeds the osmotic pressure of the exudate (horizontal lines X) considerably. Pressures expressed in the corresponding freezing point depressions as well as in atmospheres. During the time the exudate was collected and twenty-eight hours prior to the beginning of the experiment the roots of the plant were kept in aerated distilled water.—Fig. 2. Experiment similar to that of figure 1, except that during the experiment and prior to it the plant was kept in full-strength Hoagland solution.

freezing point determinations great care was taken to under-cool always to the same point ($-2^{\circ}\text{C}.$). In this way highly comparable results were obtained. The standard error of the Δ (freezing point depression) determinations was $0.004^{\circ}\text{C}.$ Differences in Δ larger than $0.010^{\circ}\text{C}.$, therefore, can be considered significant. All the Δ determinations of a single experiment were carried out at its conclusion. Samples were saved in the refrigerator until they were analyzed.

RESULTS WITH LOW SALT PLANTS.—In practically all experiments the root pressure, as measured by the compensation method with mannitol, exceeded the osmotic pressure of the exudate. In figure 1, as in the other figures, the root pressure is indicated by vertical lines (marked R) and the osmotic pressure of the exudate is indicated by horizontal lines (marked X). The length of the horizontal lines indicates the time during which the sample was collected. The plant for which the data are shown in figure 1 was decapitated at about 1 P.M., and immediately after the necessary apparatus was attached, the pressure with which water was taken up was measured (first vertical line R). During the next forty minutes 2 cc. of exudate were collected, the freezing point depression of which was $0.088^{\circ}\text{C}.$ as against $0.156^{\circ}\text{C}.$ for the mannitol solution which just checked the bleeding (R). If expressed in atmospheres, it means that the root pressure was 1.88 atm. and the exudate had an osmotic pressure of 0.46 atm. A second root pressure determination immediately following the collection of the first exudate proved to have a Δ of $0.098^{\circ}\text{C}.$ (1.18 atm.). During the next hour, following the second root pressure determination, another 3 cc. of exudate was collected having a Δ of $0.24^{\circ}\text{C}.$ (0.29 atm.). During the next hours the freezing point depression of the exudate decreased still more, reaching $0.008^{\circ}\text{C}.$ during a period which lasted from 7:35 P.M. to 6:45 A.M. the next morning. During this final period 14 cc. of exudate were collected. Although the Δ of the exudate dropped to $0.008^{\circ}\text{C}.$, the pressure with which water was taken up by the roots never dropped below a value ten times as high ($0.080^{\circ}\text{C}.$). From May 25 to June 11, nineteen root pressure determinations and seventeen exudate determinations were made within a period of seven hours after the plants were decapitated and under conditions (roots in distilled water) similar to those shown in figure 1. The average Δ of the exudate was $0.033 \pm 0.004^{\circ}\text{C}.$ (0.40 atm.). The average pressure with which the roots took up water was $0.116 \pm 0.007^{\circ}\text{C}.$ (1.40 atm.). The average difference between these two values was $0.083 \pm 0.005^{\circ}\text{C}.$ (1.00 atm.). This is the pressure with which the roots take up water in excess of osmotic pressure,³ and it is on the average 2.5 times as large as the osmotic pressure under the conditions of this type of experiment.

RESULTS WITH HIGH SALT PLANTS.—Since the results discussed above were obtained with roots which were kept in distilled water, the question arose whether similar results could be obtained if the roots

were kept in full-strength Hoagland solution. Figure 2 clearly shows that this was the case. Three days prior to decapitation the plants were given full instead of half-strength Hoagland solution. On June 2 at 12:15 P.M. a plant was decapitated and the root pressure was determined (fig. 2). It proved to be 2.75 atm. ($\Delta=0.227^{\circ}\text{C}.$). In a parallel experiment the root pressure determination made immediately after the decapitation was 3.50 atm. This was the highest value for root pressure ever found in these experiments. Not only the root pressure but also the osmotic pressure of the exudate was much higher in the high salt than in the low salt plants. In the experiment shown in figure 2 the osmotic pressure of the exudate in consecutive periods was respectively 1.32 atm. (corresponding to a Δ of $0.109^{\circ}\text{C}.$), 1.07 atm. ($\Delta=0.089^{\circ}\text{C}.$) and 0.95 atm. ($\Delta=0.079^{\circ}\text{C}.$). The amount of exudate collected during these periods was respectively 4, 3 and 7 cc., the last period lasting twenty-two hours. In a parallel experiment almost identical figures were obtained. Thus, the exudate is more concentrated than the full-strength Hoagland solution itself which had a Δ of approximately $0.070^{\circ}\text{C}.$ A further comparison between figures 1 and 2 shows that the "active" pressure,⁴ which is the difference between the root pressure and the osmotic pressure of the exudate is about equal in both high and low salt plants. The root pressures found in these experiments compare well with the ones found by Kramer (1941) who concluded that the root pressure of tomatoes that stopped bleeding due to drying out of the soil must be about 1 or 2 atm. White (1938), however, reported root pressures as high as 6 atm. in isolated tomato roots cultivated *in vitro*.

RESULTS OF EXPERIMENTS DONE OVER A PROLONGED TIME.—The experiments discussed above were discontinued after about one day, and the bulk of determinations were made within about seven hours. Tomato plants, however, may continue to bleed for longer periods (Grossenbacher, 1938, 1939; Skoog, Broyer and Grossenbacher, 1938; Heyl, 1933). Figure 3 may serve as an example. The plant was grown at $20^{\circ}\text{C}.$ and removed just prior to decapitation to $26.5^{\circ}\text{C}.$ where it stayed for the duration of the experiment. On April 22 at 12 noon the plant was decapitated and 15 cc. of exudate were collected during that day, 20 cc. were collected during the next period at the end of which the root pressure was determined (vertical line R). This procedure was repeated until April 25 noon. It is obvious from figure 3 that the osmotic pressure of the exudate has remained practically constant during the three days of the experiment. The root pressure, however, went through cycles of high and low pressures, the high pressures coming about noon. In at least three other experiments similar relatively high root pressures were found at noon, which is in agreement with Grossenbacher (1938), who reported high rates of

⁴ The part of the root pressure that cannot be accounted for on the basis of osmosis has been arbitrarily called "active" pressure to set it apart from the simple physico-chemical phenomenon of osmosis. The "active" pressure can be inhibited by KCN and the osmotic pressure cannot.

exudation occurring during that time. Although the diurnal cycle was not made a special object in this study, it seems reasonable to conclude that the cyclic increase and decrease in rate of exudation reported by Grossenbacher (1938, 1939), Heyl (1933) and many others is due to a periodic increase of the "active" part of the root pressure and not to the osmotic part. However, this may not explain the periodic increases in rate quantitatively, since it is also possible that periodic changes in water permeability exist.

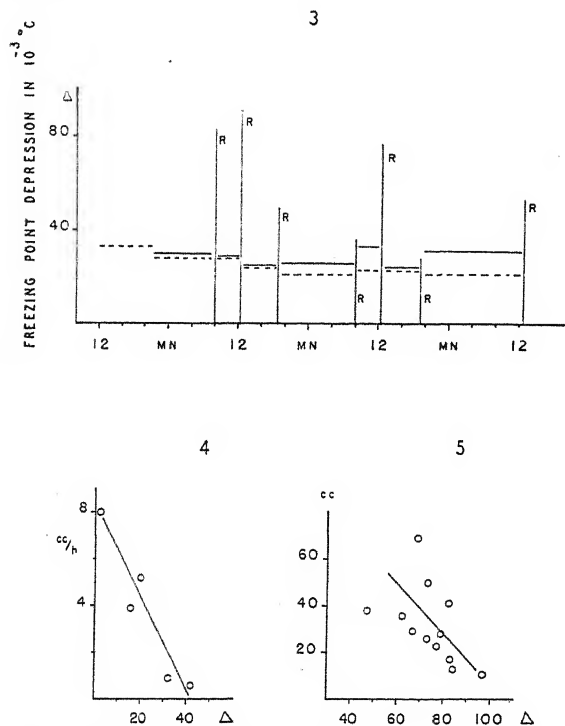

Fig. 3-5.—Fig. 3. Experiment similar to that of figure 1, but root pressure and exudate determinations were continued for three days. The osmotic pressure of the exudate was determined cryoscopically (solid horizontal lines) as well as by calculation from the conductivity (broken lines).—Fig. 4. Negative correlation between the rate of bleeding (ordinate) and the osmotic pressure of the exudate. The latter expressed in the corresponding 10⁻³°C. freezing point depression (abscissa). The rate of bleeding was controlled by suction on the cut stem. Root system in distilled water during the experiment.—Fig. 5. Negative correlation between the total amount of exudate collected per plant in one week (ordinate) and its average freezing point depression (solute concentration; abscissa). Tomato plants grown in subirrigated gravel culture.

COMPOSITION OF THE EXUDATE.⁵—Except in the first sample of exudate, collected shortly after decapitation, sugars were absent in the exudate. In the first sample both glucose and sucrose were found in concentrations which rarely exceeded 0.01 per cent. This agrees with the findings of Crafts (1936)

⁵ I wish to express my thanks to Mr. E. L. Grady who carried out the sugar analyses and to Mr. Alan Bell who did the conductivity determinations.

that no phloem exudate appeared more than a few hours after a cut had been made. Conductivity measurements were carried out on a large number of samples taken during the earlier stages of the experiments. On the assumption that the osmotically active material of the exudate has a conductivity equivalent to KCl, the Δ was calculated from conductivity data. For forty-three instances the calculated Δ was on the average only 0.005 ± 0.001 °C. less than the actual Δ . This calculated Δ is drawn into figure 3 as dotted horizontal lines as compared with the solid lines, which represent the actually determined freezing point depressions of the exudate. The exudate, therefore, may be considered to consist almost exclusively of electrolytes.

The pH of the first sample of exudate was between 5.5 and 6.0 and increased with the time after decapitation. Two days after decapitation the pH often was slightly greater than 7.0. Plants that still bled after eight days were found to have a pH of 8.5. The exudate of plants grown in gravel and subirrigated with Hoagland solutions which were adjusted daily to pH 3, 5, 4.5 and 5.5 had the same pH of 5.5 regardless of the pH of the medium. The gradual increase in pH with time after decapitation was the same as in plants grown in culture solutions. However, the concentration of the exudate, as determined by the freezing point depression, is dependent upon the rate of bleeding. A slowly bleeding plant usually has a more concentrated exudate than a fast bleeding one (fig. 4 and 5).

RELATION BETWEEN THE RATE OF BLEEDING AND THE Δ OF THE EXUDATE.—The conclusion that the difference between the root pressure and the osmotic pressure of the exudate represents the pressure with which water is taken up by "active" forces stands or falls with the assumption that the exudate represents the sap in the vessels of the water-absorbing region of the root. One could assume that the "active" pressure is only apparent because the Δ of the exudate might be far lower than that of the sap in the vessels of the root. One could suppose that this condition could be brought about by absorption of solutes in the course of the upward movement of the xylem contents. This is unlikely, however, because accumulation of solutes by the roots was excluded by placing the roots in distilled water during the experiments. Furthermore, if during the experiments solutes were removed from the xylem, one would expect that a slowly bleeding plant would have a less concentrated exudate than a faster bleeding plant. Exactly the reverse is true. This is shown in figure 4 where the rate of bleeding was varied by using suction (Kramer, 1933). A slow-moving exudate was actually more concentrated than a fast-moving one, which may indicate that some solutes were given off into the xylem. In agreement with this is the observation that at the end of prolonged experiments or after severe treatment with KCN the root pressure always was somewhat below the osmotic pressure of the exudate (fig. 6B). As long as the root system was still alive the root pressure remained at this

level and never was found to drop to zero, not even under conditions of severe irreversible narcosis. This is in agreement with Rosene (1941b) who observed the same for the rate of bleeding. The semi-permeability of the membranes was still intact under these conditions because the rate of bleeding could be changed by changing the concentration of mannitol solutions around the roots. The above is interpreted to mean that in old plants and in narcotized plants the root pressure equals the osmotic pressure of the sap of the xylem of the roots, that the osmotic component of the root pressure remains and that the "active" pressure has disappeared.

FURTHER EXPERIMENTS SHOWING THE DUAL CHARACTER OF ROOT PRESSURE.—The conclusion that the root pressure is made up of two components, (1) osmotic pressure and (2) "active" pressure, would be considerably strengthened if the components could be reversibly separated. The "active" pressure might be assumed to depend upon respiratory processes just as the accumulation of solutes by the roots (Hoagland and Broyer, 1936) or by other tissues (Steward, Stout and Preston, 1940). If the assumption is correct, one might be able reversibly to cut out the "active" component of the root pressure by using KCN. Figure 6 shows that this can be done. The plants used for these experiments were grown for $2\frac{1}{2}$ weeks in the solution suggested by Arnon and Hoagland (1940, p. 477) and had a very vigorous root system. Fifteen minutes after a plant was decapitated and its root system transferred to distilled water the root pressure was measured by means of the mannitol method described above. Immediately after this determination the roots were transferred to 10^{-4} M KCN (fig. 6A). The solution was stirred by bubbling air through it. After one hour the rate of bleeding had dropped to 50 per cent of its original value and mannitol was added to the KCN solution in order to determine the root pressure of the plant in this condition. It had dropped considerably as can be seen in figure 6A. Immediately after this root pressure determination the root system was removed from the KCN solution, rinsed and replaced in distilled water. One hour later the root pressure had returned to almost its original value. After this final root pressure determination, 4 cc. of exudate was collected in three hours, which had a Δ of 0.015°C .

A parallel experiment gave identical results. The first root pressure determination gave a Δ of 0.145°C . The root pressure after one hour in 10^{-4} M KCN gave a Δ of 0.077°C ; one hour after the root system had been returned to distilled water it was 0.125°C . In the following three hours 6 cc. of exudate were collected having a Δ of 0.020°C . The rate of bleeding of this plant was originally 150 arbitrary divisions of the potometer tube. After one hour in 10^{-4} M KCN it dropped to 70, to recover to 170, one hour after the roots were brought back in distilled water.

Figure 6B shows a similar experiment except that a ten times higher KCN solution was used for a

shorter period of time. The root pressure was reduced to less than 25 per cent of its original value, which is slightly below the osmotic pressure of the exudate. From experience with relatively high concentrations of HCN one could say that, even if the roots were kept for a longer time in this KCN solution, the root-pressure would have dropped no more, but this drop would not have been reversible as it was in this experiment (fig. 6B).

Fig. 6 A-B.—Fig. 6A. Reversible reduction of part of the root pressure by means of immersion of the root system in 10^{-4} M KCN for one hour (shaded part of the diagram). The rate of bleeding during the experiment is indicated by a broken line. Plants decapitated thirteen minutes before the first root pressure determination was started.—Fig. 6B. Same as figure 6A except for concentration and time of exposure to KCN. Even during severe exposure to HCN when the reduction in root pressure is no longer reversible, the root pressure was never found to drop completely to zero, as long as semi-permeability is retained.

DISCUSSION.—The great difference between the osmotic pressure of the exudate and the pressure with which the excised root system takes up water (fig. 1, 2, 3) makes it impossible to explain the entire phenomenon of root pressure on the basis of osmosis. The reversible separation of the "active" component of the root pressure by KCN makes it seem very likely that part of the water uptake of roots is connected with respiratory processes or at least with reactions involving heavy metal catalysis. In this connection it may be instructive to draw a parallel between this form of water uptake and the accumula-

tion of solutes by roots. Hoagland (1936) and Hoagland and Broyer (1936) showed that accumulation of solutes by excised roots is greatly dependent upon aerobic respiration. Similarly Steward (1933) showed that only strongly metabolizing cells of potato disks are capable of accumulating KBr. Rosenfels (1935) showed a close connection between respiration and solute accumulation in *Elodea*. What the actual mechanism of the "active" water uptake by roots really is remains a mystery for the time being. However, Keller (1930) in the second part of a voluminous paper dealing with water transport as an electrical phenomenon, believes that root pressure is due to electro-osmosis. The prerequisite for electro-osmosis is a potential difference across a membrane, a condition which may very well be realized in actively metabolizing root cells. Blinks (1940) has shown that the potential difference across the protoplasm of cells of *Halicystis* is distinctly under metabolic control (low oxygen, high CO₂, light, poisons, etc.). Blinks (personal letter), however, considers electro-osmosis unlikely because the current flow is probably not sufficient and the salt concentrations in cells are unfavorably high for electro-kinetic phenomena.

SUMMARY

The osmotic pressure of the exudate of decapitated tomato plants, grown in culture solution, is considerably lower than the pressure with which the roots absorb water. The latter pressure (root pressure) was determined as the osmotic pressure of a mannitol solution, placed around the roots, which reduces the rate of exudation exactly to zero.

It is concluded that the pressure with which healthy root systems of decapitated tomato plants absorb water is made up of two components: (1) an "active" pressure,⁴ and (2) a pressure of osmotic origin. Roots kept in distilled water during the experiment developed an average root pressure (determined cryoscopically by means of mannitol solutions) of 1.40 atm., of which 71 per cent was "active" pressure and 29 per cent pressure of osmotic origin. Roots kept in Hoagland solution during the experiment absorbed water with an average pressure of 2.68 atm., 48 per cent of which was "active." The active component of the root pressure could be reversibly eliminated by means of KCN.

RESISTANCE OF WATERMELON TO THE WILT DISEASE¹

Albert E. Braun

THE SEEDLINGS of most edible varieties of watermelon, *Citrullus vulgaris* (Schr.), are highly susceptible to the wilt disease caused by *Fusarium oxysporum* f. *niveum* (E. F. S.) Snyder and Hansen, except those which have been bred for resistance by crossing with the Citron, a non-edible, less susceptible variety.

In a previous investigation to ascertain the causes of susceptibility to the wilt disease, Braun (1937) found no evidence that differences in susceptibility were due to anatomical variation. With this in view it was thought that differences in susceptibility might be due to the presence or relative abundance of a chemical compound.

Two varieties of watermelon were chosen for this study: A very susceptible variety, Kleckley Sweet (not the improved Kleckley Sweet) and a less susceptible variety, Citron. The Citron is not immune to the wilt disease, but the rate of growth of the fungus is very slow in the Citron as compared to the more susceptible varieties. Plants were grown in the field and harvested when six weeks old, dried in an oven at 60°C. and ground to a fine pulp. Stems and roots were kept separate. Samples of the pulp were refluxed in water for three hours and small portions of the water extract were placed in liquid culture media inoculated with *Fusarium oxysporum* f. *niveum* spores. After two weeks the cultures were examined, and the medium with the Citron shoot extract contained considerably less growth than the control. No differences from the control were observed in the cultures with the Citron root extract, the Kleckley Sweet root extract nor the Kleckley Sweet shoot extract. The sample pulp samples were dried and refluxed with ether for three hours. The ether was decanted and allowed to evaporate. The fatty material was suspended in water, and samples of each extract were placed in culture media and inoculated with *Fusarium oxysporum* f. *niveum* spores. None of the material extracted with ether had any influence on the growth of *Fusarium oxysporum* f. *niveum*. These results indicated that the water soluble extract contained a substance which has some relationship to susceptibility, and further tests showed that the material was a volatile acid. To determine the nature of the volatile acid, 500 g. of pulp of each variety were placed in separate distilling flasks, and water slightly acidified with sulfuric acid was added. One liter was distilled from each flask, neutralized with sodium hydroxide and

evaporated to the dry salt. From this was obtained 0.126 g. of salt from the Citron shoot distillate and 0.017 g. of salt from the Kleckley Sweet shoot distillate. The salts were analyzed for their acid constituents according to the method of Schickstanz, Steele, and Blaisdell (1940). The salt obtained from the Kleckley Sweet variety when distilled with toluenesulfonic acid in benzene or toluene gave no significant titration with 0.1 N sodium hydroxide. However, the salt obtained from the Citron variety when distilled with toluenesulfonic acid and benzene gave results as shown on table 1. The amount of acid per fraction indicates the presence of acetic acid. However, under the conditions of isolation it cannot be claimed that acetic acid is found in the free state in the plant. No significant titration was obtained with toluene.

TABLE 1. Fractional azeotropic distillation of the mixture in benzene; titrated with 0.1N sodium hydroxide. (Acid liberated from sodium salt with toluenesulfonic acid.)

Volume of fraction	0.1N NaOH
ml.	ml.
10	2.55
10	1.00
10	0.75
100	6.50
30	1.80
90	1.35

The fractional distillates which had been neutralized with sodium hydroxide were evaporated to dryness and redissolved in water slightly acidified with sulfuric acid and distilled. A sample distillate from each solution was tested for its action on the growth of *Fusarium oxysporum* f. *niveum*, but only the solution from the Citron shoot retarded the growth of the fungus. It is well known that the pathogen enters the root system of the seedlings, becomes established there and initiates the disease in both the susceptible variety and the more resistant Citron. The growth of the fungus in the Citron is apparently retarded by something from the shoot, which may be acetic acid, and not from the root itself, for the pathogen becomes established in the root system of either variety.

The action of acetic acid was also tested on the growth of the fungus, and it was found that one part of acetic acid in one hundred parts of nutrient solution completely inhibited the growth of the fungus,

¹ Received for publication April 27, 1942.

The author wishes to thank Mr. Donald Bolin of the Agricultural Chemistry Department, University of Idaho, for suggestions and the use of certain equipment.

while one part of acetic acid in five hundred parts of nutrient solution slightly retarded the growth of the fungus.

SUMMARY

In this investigation more acetic acid was found in the Citron, a variety of watermelon less susceptible to the wilt disease, than in Kleckley Sweet, a more susceptible variety. However, further investigations will be necessary to prove definitely that the acetic acid is the basis of resistance to the wilt disease.

POSTGLACIAL MIGRATION OF FIVE FOREST GENERA ¹

Paul B. Sears

THE FOLLOWING study presents evidence concerning the postglacial movements of *Quercus*, *Tsuga*, *Carya*, *Fagus*, and *Tilia*. The area under consideration extends eastward from Minnesota and Iowa to the Atlantic Coast, and from the St. Lawrence Valley southward to Virginia and Tennessee.

The evidence has been secured by determining the relative order of appearance of the pollen of the above genera in 117 bog profiles, taken from 111 bogs distributed over the area. Of these profiles, eighty-five are from the published work of others, while thirty-two are based upon analyses made by the author or under his direction. Two of the thirty-two analyses have been published, thirteen are in press, and the remaining seventeen are on file at Oberlin.

The data for each of the five genera are mapped separately, the numbers 1 to 5 being used as symbols. The position of the symbol on the map indicates the location of the profile in question. The number itself indicates the order in the sequence, beginning at the bottom of the profile, of the first trace of pollen of the genus. Where two or more kinds of pollen make their first appearance at the same level, they are given the same number.

Within the limitations of the procedure, each map should indicate: (a) the areas of first appearance of the genus after the beginning of sedimentation and (b) the direction and extent within the area of subsequent movement. It must be emphasized that this procedure is tentative, as any reconstruction of the past must be. It should, however, open up a useful approach and point the way for critical and intensive local studies.

In addition, this information regarding sequence and direction of movements is here correlated with the results of a paper now in press (Sears, 1942), dealing with postglacial forest sequences within the area. Both papers continue investigations begun in 1916 on the historical factor in natural vegetation (Sears, 1926). The paper now in press reports fairly consistent evidence from Illinois, Indiana, Michigan,

and Ohio of the existence in postglacial times of two intervals of diminished mesophytism, separated by a relatively more mesophytic interval (see also Auer, 1930; Sears, 1931).

Since such apparent lessening of mesophytism seems to represent reversal or interruption of the normal course of forest succession, I have designated it as "retrogression" (Cowles, 1901). And since it is widespread, I have inferred that it was due, in both instances, to a decrease in available moisture. The resulting scheme is as follows:

- V. The present—probably cooler and with more available moisture than in IV.
- IV. A warm dry period—maximum of oaks and hickories, minimum of beech.
- III. A more humid, also warm, period—maximum of beech, and, in places, of hemlock.
- II. A dry, probably warmer, period—maximum of pine, often with oak.
- I. A moist cool period—maximum of fir and spruce.

The Roman numerals are here used as in the preceding paper, and are to be so understood hereinafter.

Allowance must be made for numerous and considerable sources of error, of which the following appear to be the most serious:

(1) Most analyses are based upon a single boring, although often checked with (unpublished) parallel borings. However, where two analyses of the same deposit do not agree in the exact order of appearance of the five genera, both have been mapped.

(2) The analyses studied have been prepared by many different workers and are not all equally detailed. In some instances the necessary details were obtainable by correspondence and reference to original notes. The most serious lack of detail involves twenty-eight bogs of southeastern Canada where the counts for *Quercus*, *Tilia*, and *Ulmus* have been lumped (Auer, 1930).

(3) The desired information may be concealed by the fact that, in relation to glacial retreat, sedimentation may not have begun at the same time in all otherwise comparable basins. Thus in younger de-

¹ Received for publication April 27, 1942.

I wish to thank Professor Emeritus Frederick O. Grover for many valuable suggestions.

posits more than one genus may be represented by pollen in the lowest level, although the genera may have entered the area at different times.

(4) The intervals of sampling are often arbitrary, in some studies as far as a meter apart. This makes it easy to miss the first appearance of a particular pollen, and may exaggerate the number of apparently simultaneous appearances.

(5) The ecological range of species within the genus *Quercus* is considerable, and it is not practicable to distinguish oak pollens specifically. On the basis of published succession charts, tolerance tables, and personal observation within the area, I have assumed that, in general, oak and hickory are less mesophytic than beech. Certainly the most mesophytic of the oaks in the North Central States, *Quercus borealis maxima*, may be succeeded by beech. This oak also extends farther toward the grassland formation than does beech.

(6) The genus *Pinus* likewise includes a wide ecological range of species. In general, however, I have assumed that the genus is indicative of less available moisture than are *Abies* and *Picea*.

To offset in a measure these various difficulties there are (a) the number and distribution of profiles studied and (b) the general consistency of the maps.

Before the maps for the genera are discussed, the following tables will show the number of profiles in which each genus was not represented, or if present, the order of its appearance. The region covered is diverse climatically and edaphically. If, however, the data be divided to include northern Michigan, northeastern Ohio, Pennsylvania, New York, New England, and Canada in one group, and the rest of the area in the other group, the following relationships appear (tables 1 and 2):

TABLE 1. *Northeastern Area (forty-eight profiles).*

	Absent	1st	2nd	3rd	4th	5th
<i>Quercus</i>	1	42	5	0	0	0
<i>Tsuga</i>	2	30	16	0	0	0
<i>Fagus</i>	20	10	9	9	0	0
<i>Carya</i>	32	5	7	1	3	0
<i>Tilia</i>	33	2	7	4	0	2

TABLE 2. *Southwestern Area (sixty-nine profiles).*

	Absent	1st	2nd	3rd	4th	5th
<i>Quercus</i>	3	63	3	0	0	0
<i>Tsuga</i>	31	10	9	11	6	2
<i>Fagus</i>	44	8	7	7	2	1
<i>Carya</i>	19	17	23	8	1	1
<i>Tilia</i>	18	15	12	18	5	1

Unfortunately, for twenty-eight bogs studied by Auer in southeastern Canada and included in these tables, *Quercus* and *Tilia* are listed together, while no mention is made of *Carya*. In spite of this fact, the tables show (a) the very general early movement of

Quercus, (b) the precedence of *Tsuga* and *Fagus* over *Carya* and *Tilia* in the northeastern area and (c) the precedence of *Carya* and *Tilia* over *Tsuga* and *Fagus* in the more continental area to the southwest.

QUERCUS (fig. 1).—Although the map for *Quercus* contains only eighty symbols, yet it gives the general distribution of the 111 bogs studied. In many cases a single symbol serves for more than one bog in a vicinity. Of the four bogs showing no trace of *Quercus*, three are in northern Wisconsin, and one (Bowman, 1931), the farthest north, is near the Moisie River on the north shore of the St. Lawrence (cf. map of *Tsuga*, fig. 2).

In eight scattered locations, *Quercus* is second in order, being preceded by *Tsuga* in Quebec, Connecticut, Pennsylvania, and Michigan; by *Fagus* in Massachusetts; by *Carya* in Indiana, Michigan and Virginia. In all other instances—105 profiles—it is first in order, with or without other of the five genera accompanying it.

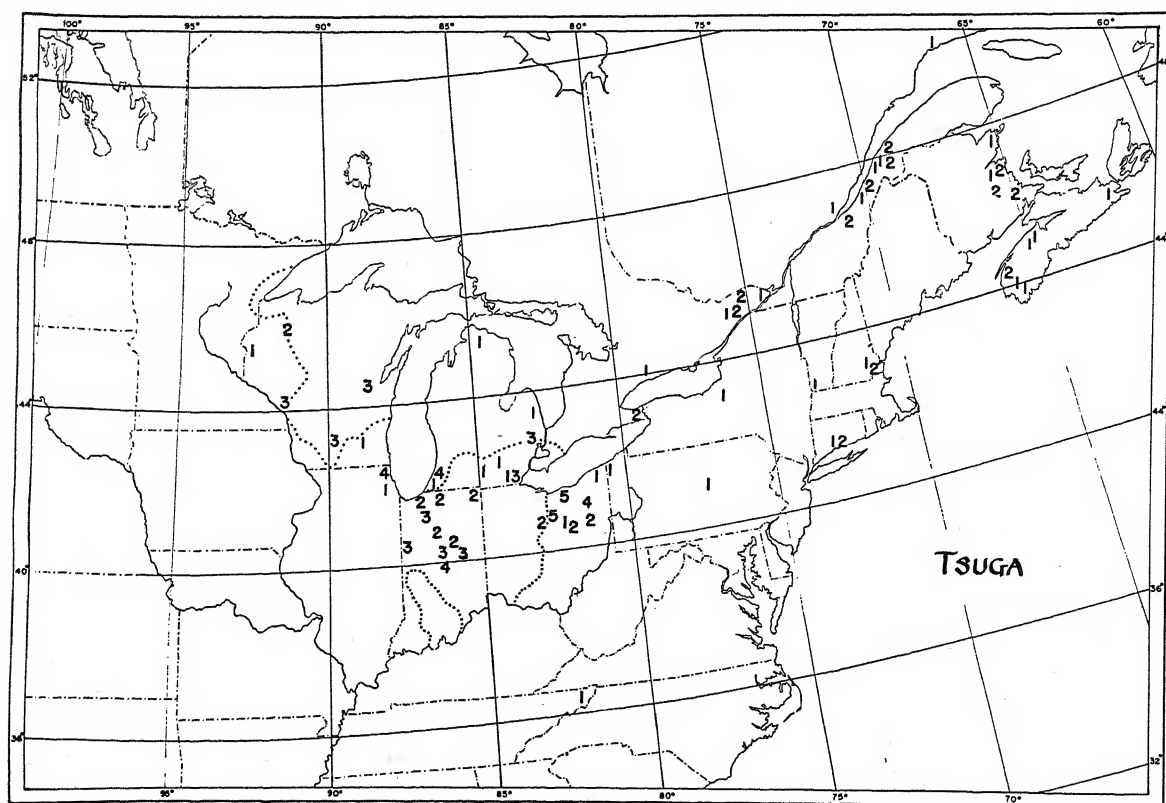

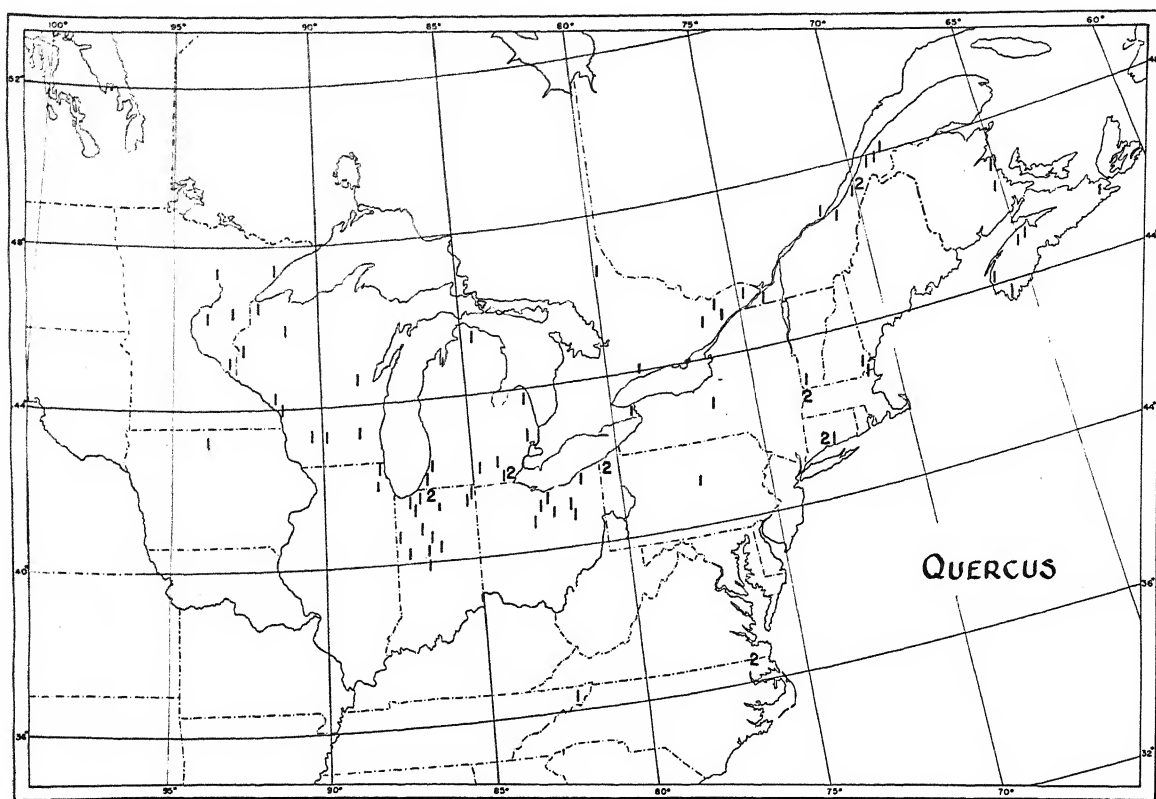

In Ohio deciduous pollen including that of *Quercus* is generally preceded by pollen of *Abies* and *Picea* (Period I), with interesting exceptions as at the glacial margin near Canton (Sears, 1942). Likewise in Indiana, *Abies* and *Picea* generally precede *Quercus* (Prettyman, 1937; Smith, 1937; Otto, 1938, et al.).

However, in the group of bogs in Illinois, Wisconsin and Minnesota described by Voss (1934), oak is present with these conifers and with *Pinus* at the lowest levels. It is also present, with *Pinus* in the lowest levels of the southeastern Canadian bogs described by Auer (1930). Auer, for other reasons, considers these latter bogs to have been initiated in a relatively dry period. Being farther north than those of Ohio and Indiana, they are younger.

Throughout the entire area, as *Abies* and *Picea* are replaced by *Pinus*, there is a noticeable increase in *Quercus*. Thus the general early diffusion of *Quercus* took place during Period II, except in the states bordering the continental grassland, where a suitable continental climate may have prevailed earlier. If my interpretation is correct, Period II and the later Period IV involved eastward extensions of these continental climatic conditions.

The supposed dryness of Period II may have been due to a rise in temperature rather than to a decrease in precipitation. Such a rise in temperature is to be inferred from the known northward retreat of *Abies* and *Picea*.

TSUGA (fig. 2).—The following facts are to be noted from the map of this species. (a) Its earliest appearances tend to be along the Atlantic coast, the St. Lawrence Valley, and in the region of the Great Lakes, including Wisconsin. (b) A number of its later appearances are within those parts of the "prairie peninsula" of Transeau (1935), where it is not now found. Compare the present western limits of its range, as indicated by broken line. (c) In numerous instances it comes in after oak in the St. Lawrence Valley.

Together with the other four genera studied, *Tsuga* is found at the bottom of the profile in eastern Tennessee, consistent with the general belief that this was a region of refuge during glaciation.

A composite pollen spectrum of two samples of peat from the Brooklyn Navy Yard, said to be part of an extensive bed or beds in the Long Island Region, is shown in figure 3 (Sears, 1941b). The spec-

Fig. 3. Pollen analysis of two samples of submerged peat from the Brooklyn Navy Yard, showing relative percentages of various forest trees. *Alnus* and *Betula* are included together.

trum of this peat shows pollen of pine and hemlock, accompanied by oak and other deciduous genera.

This peat is said to be underlain by (boulder?) clay which rests on bed rock and is overlain by outwash gravel. It is about 60 feet below the present surface of Long Island Sound, but, relative to sea level, stood about 100 feet higher during the last glaciation than it does today (Antevs, 1928). This would have placed the surface on which the peat lies at least 40 feet above water. Antevs (1928, p. 90) states that the postglacial submergence "was a very slow process going on until a few thousand years ago." This gives some reason for supposing that the peat is not interglacial. Furthermore, the peat, while compressed, is relatively fresher than most interglacial peat I have examined, again suggesting a postglacial origin.

Whatever the age of this deposit, it is clear that any portion of the continental shelf exposed at the beginning of postglacial time was then available for the northward movement of vegetation. Antevs (1928, p. 91) believes it possible that "part of the now submerged coastal plain may still have been land when the temperature had risen higher than that now prevailing."

If the continental shelf were still above water during Period II, and if warming were chiefly responsible for the relative dryness of this period, both *Tsuga* and *Quercus* may well have moved northward on it during that time. This would apply not only to any coastal route, but equally to interior routes near enough the ocean not to be unfavorable to *Tsuga*.

Furthermore, the increase of *Tsuga* in southeastern Canada should have been definitely favored by the subsequent, warm and more humid Period III which I believe to have existed. This accords with the views of Auer (1930), who comments on the similarity of behavior between *Tsuga* and the deciduous trees. Even in Canada, eleven of the twenty-eight profiles containing both *Tsuga* and *Quercus* show *Tsuga* following *Quercus*.

On the other hand, it is clear from the map that while *Tsuga* either accompanies or follows *Quercus*

in the St. Lawrence Valley and Nova Scotia, it is relatively later in Indiana. The assumed dryness of Period II would certainly have delayed any movement of this genus toward the continental interior. Moreover the supposedly humid Period III offers a reasonable explanation of the relatively late appearance of *Tsuga* in and near those parts of the present prairie peninsula in Ohio and Indiana where it is not now found. The map affords no basis for believing that, in this region, *Tsuga* persisted *in situ* from an earlier, purely coniferous phase, since its pollen is not reported from lower levels. Its appearance here seems to have been merely an intrusion during a favorable mesophytic interlude, followed by withdrawal under less favorable conditions later. It is to be noted that *Tsuga* still persists in southwestern Indiana and in Kentucky, but no pollen profiles are available from this important direction.

Several early occurrences of *Tsuga* are also to be noted, a little beyond its present range limits in Wisconsin, Illinois, and Michigan. In these cases *Tsuga* is definitely associated with the early conifers. These facts suggest an early center of diffusion within the Wisconsin Driftless Area, doubtless a refuge during glacial times and still partly within the range of *Tsuga*.

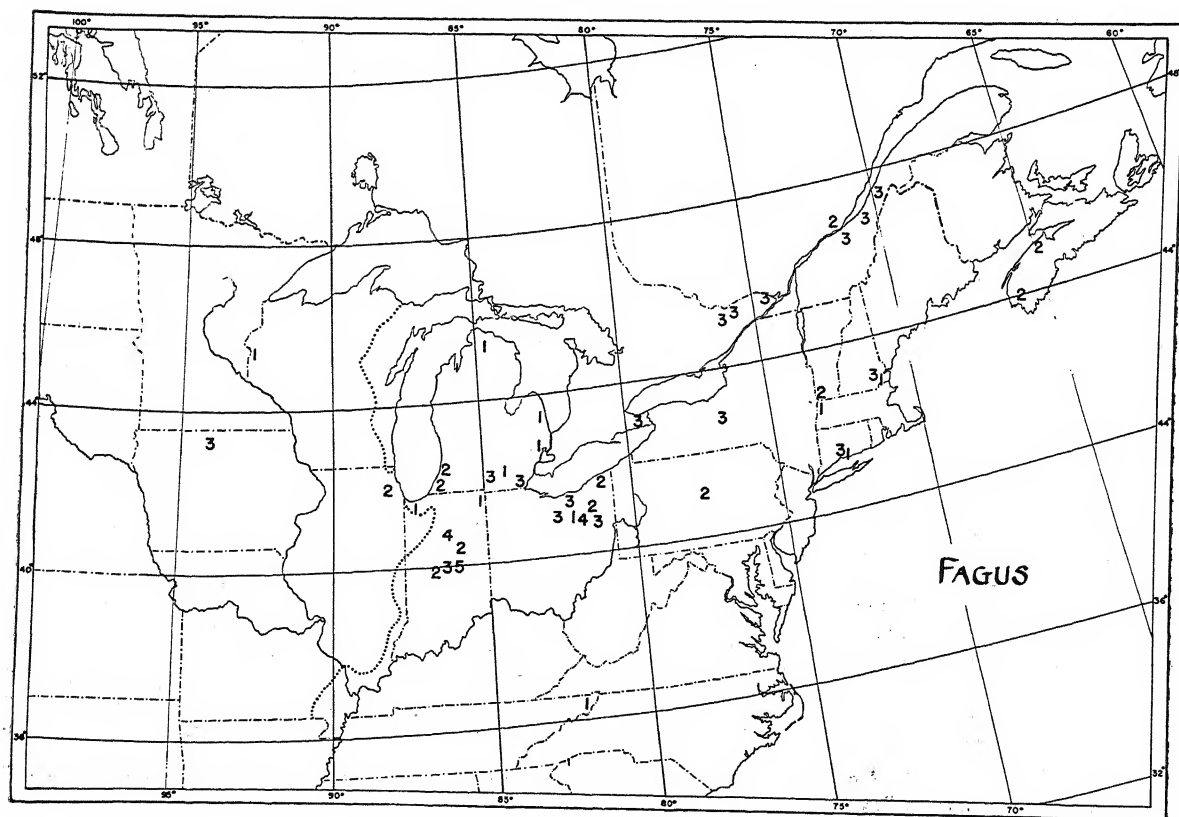

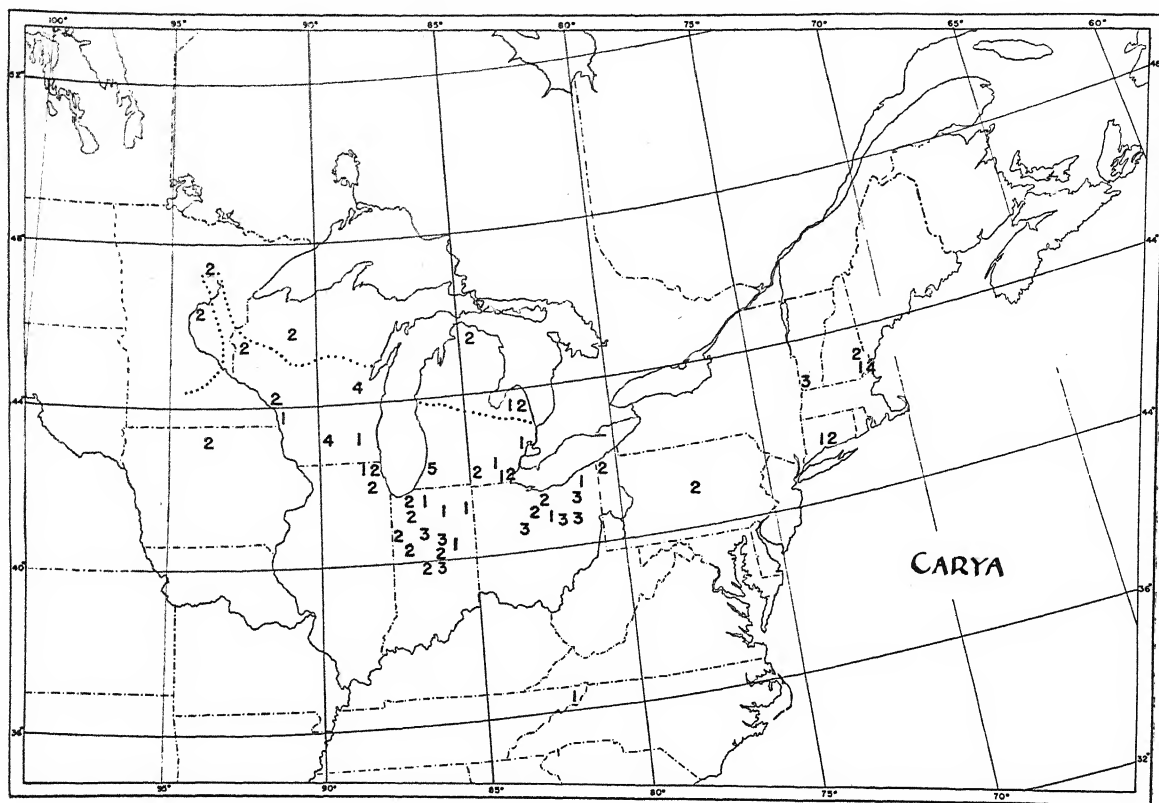

CARYA (fig. 4).—Information regarding this genus is lacking for southeastern Canada. Elsewhere it is relatively early; fifty-two of its sixty-six appearances are either first or second in the series. It is at the first level in Tennessee, Virginia, Connecticut, and New Hampshire. This bespeaks its migration northward along the Atlantic coast. It is also present in the submerged Long Island peat.

Elsewhere its early occurrences are at the periphery of the prairie peninsula and in the Wisconsin Driftless Area and re-entrant. Conceivably it may have moved northwest into the Great Lakes region along routes not revealed by the present study. Data from the lower Ohio Valley are needed and a most detailed study of sediments in and near the Driftless Area should be made.

Profiles from the North Central States rather frequently show *Carya* present with *Quercus* during Period II. This was followed by a relative decrease during Period III with a subsequent maximum during Period IV.

Most interesting, however, is its behavior with reference to the present northern range limit of the genus, as shown by a broken line based upon data from Messrs. Darlington, Fassett, Goodman, and Lawrence. *Carya* pollen occurs in four profiles north of its present range, and in another profile in Itasca County, Minnesota, where its modern occurrence is sporadic. In all of these five profiles its behavior is identical. It shows as a trace, and only at the level of the distinct oak maximum which marks Period IV. This oak maximum is characteristic of many bogs in the southern part of the present coniferous region (Sears, 1935) and corresponds to the only ap-

Fig. 1-2.—Fig. 1 (above). Map showing relative order of appearance of *Quercus*.—Fig. 2 (below). Map showing relative order of appearance of *Tsuga*.

pearance of oak (q.v.) in the bog north of Georgian Bay (Janson and Halfert, 1937).

The apparent northward advance and subsequent retreat of *Carya* thus supports the idea that Period IV was a time of maximum warmth during postglacial time. Farther south the decrease of *Fagus* and *Tsuga* during Period IV and the accompanying increase of *Quercus* and *Carya* afford a basis for believing that it was also relatively drier than Period III.

These circumstances, together with abundant direct evidence from profiles in the North Central States and southeastern Canada, indicate strongly that the range of *Fagus* expanded during Period III and retracted during the subsequent drier Period IV.

Pending the necessary critical studies, the suggestion is offered that *Fagus* had a glacial refuge in the Driftless Area of Wisconsin as well as one in Tennessee. Data from the lower Ohio and Missouri Valleys should be of great interest.

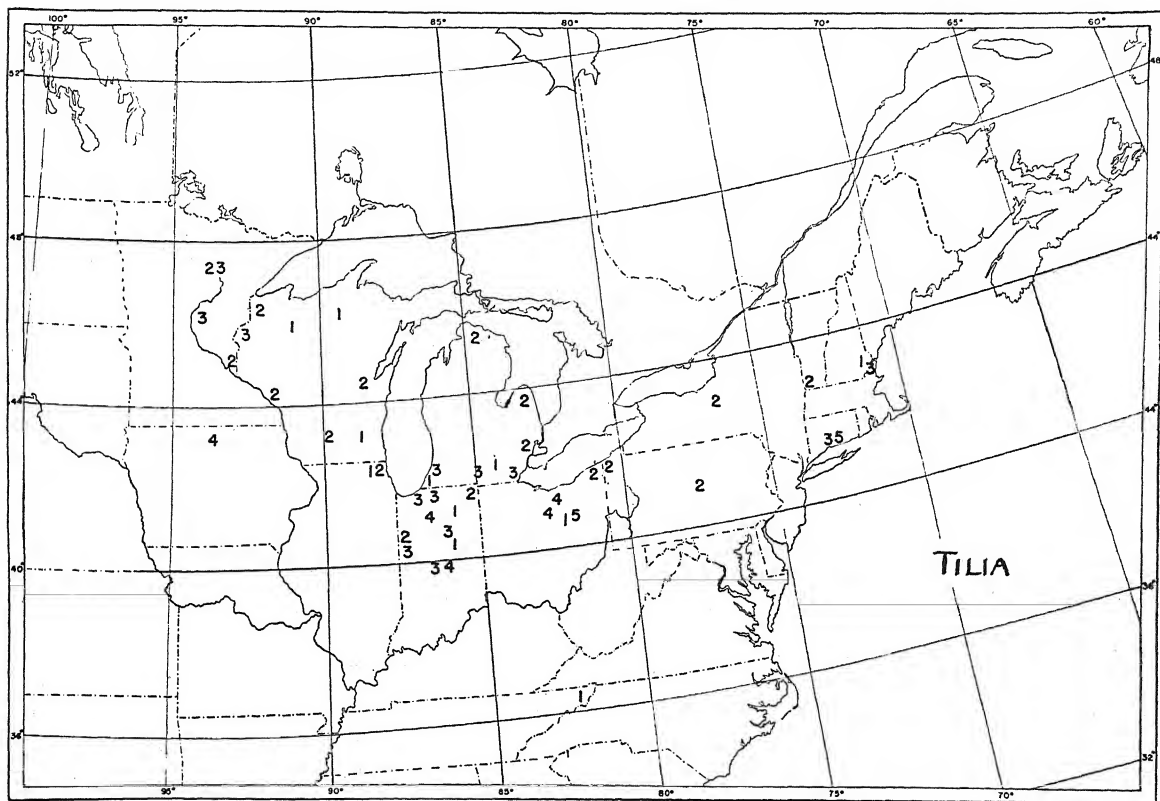

Fig. 6. Map showing relative order of appearance of *Tilia*.

Fagus (fig. 5).—*Fagus* appears first in order along the Atlantic coast, in Connecticut, Massachusetts and New Hampshire. It obviously follows *Quercus* and *Tsuga* in the St. Lawrence Valley. Other early occurrences were in the western portion of the area at the edge of the prairie peninsula, near the Driftless Area and over the southern peninsula of Michigan. The apparent movement of beech into central Indiana resembles that already described for *Tsuga*.

Especially notable are three records for *Fagus* in Iowa, Wisconsin, and Illinois, respectively, which clearly lie to the west of the present critical limits of this genus as outlined by Transeau (1935) and shown here by a dotted line.

Fagus is specialized, requiring humid conditions and occupying a late stage in forest succession.

TILIA (fig. 6).—Unlike *Carya*, *Tsuga*, and *Fagus*, this genus does not appear in any profiles outside of its present range. It shows relatively few early stations, namely one in New Hampshire, several at the periphery of the prairie peninsula, and two, very definitely, in northern Wisconsin. Its movement westward from Wisconsin into Minnesota and Iowa, where it followed *Fagus*, seems clearly indicated.

Whether it entered from a southwestern refuge, or persisted in the Wisconsin re-entrant, or both, its early appearances in Wisconsin, Illinois, Indiana and Michigan represent its position during Period II. Its movement to the west and southwest was subsequent, apparently favored by the more humid Period III, as were *Fagus* and *Tsuga*. But unlike them, it was able to hold its ground and even to advance beyond the Missouri River, where today, with

Fig. 4-5.—Fig. 4 (above). Map showing relative order of appearance of *Carya* (add 1 at location of Dismal Swamp, Virginia).—Fig. 5 (below). Map showing relative order of appearance of *Fagus*.

Quercus borealis maxima, it represents the most mesophytic stage of forest succession (Pool, Weaver and Jean, 1918).

SUMMARY

The relative order of appearance of pollen of *Quercus*, *Tsuga*, *Carya*, *Fagus*, and *Tilia* in 111 peat deposits within an area extending from Iowa to the Atlantic, and from Tennessee to the St. Lawrence is here reported. Resultant inferences concerning order, direction, and extent of migration are discussed in relation to supposed changes in postglacial climate.

The general order of appearance in the northeastern part of the area was apparently: *Quercus*, *Tsuga*, *Fagus*, *Carya*, and *Tilia*; in the southwestern part: *Quercus*, *Carya*, *Tilia*, *Tsuga*, and *Fagus*.

The early and general dispersal of *Quercus* seems to have occurred when *Pinus* replaced *Abies* and *Picea*. This shift in composition coincides with a supposed dry period, possibly resulting from rising temperature rather than from decreased precipitation. *Tsuga* appears to have accompanied *Quercus* into eastern Canada at this time in the relatively moister climate of the Atlantic region. In the interior, *Quercus* was frequently accompanied by *Carya*.

Later the ranges of *Tsuga* and *Fagus* apparently expanded, not only within southeastern Canada, but farther west into the area beyond the present limits of these genera. This is regarded as an indication that climate in the continental interior was then more humid than it had been just previously. *Tilia* also seems to have moved westward, during this more humid time, toward its present limits.

After that, *Carya* evidently extended north of its present general limits. This extension is definitely correlated with a decrease in *Tsuga* and *Fagus* and with a maximum of *Quercus* in the coniferous bogs at the northern edge of the area. It is regarded as indicating a second dry and warm period, now past its climax.

Important early centers of dispersal appear to have existed in the southeastern part of the area and in Wisconsin, a considerable part of which was not covered by the last glaciation.

This does not preclude the existence of other early dispersion centers and routes which may be revealed when the necessary intensive local studies are made. Data from the lower Ohio Valley should be of especial importance.

PACIFIC SECTION

ABSTRACTS OF THE PAPERS PRESENTED BEFORE THE PACIFIC SECTION OF THE BOTANICAL SOCIETY OF AMERICA, SALT LAKE CITY, UTAH, JUNE 15 TO 18, 1942

SOME DESMIDS OF UTAH. *Seville Flowers, University of Utah, Salt Lake City, Utah.*—The present account of Utah desmids is a list of species collected over a period of twenty years together with data and notes citing previous records. The principal localities in which they were collected center around the lakes in the Uintah Mountains and Wasatch Mountains. A few other localities are included. At present about one hundred twenty-five species and varieties are sufficiently well known to be included in this list. Others are still lacking definite confirmation and may be published later.

The following is an enumeration of the genera and species to be cited in the complete paper: *Arthrodesmus*, five species; *Calocylindrus*, two species; *Closterium*, nineteen species; *Cosmarium*, thirty-two species; *Euastrum*, thirteen species; *Desmidium*, two species; *Gymnozyga*, two species; *Hyalotheca*, one species; *Micrasterias*, fourteen species and varieties; *Netrium*, three species and varieties; *Pleurotaenium*, three species; *Sphaerosozma*, two species; *Spirotaenia*, one species; *Stauroastrum*, twenty-one species and varieties; *Xanthidium*, seven species and varieties.

FURTHER STUDIES ON THE SAPROLEGNACEAE OF SOUTHERN CALIFORNIA. *James V. Harvey, San Bernardino Valley Junior College, San Bernardino, California.*—Central and northern California stations have offered a few species of the true water-molds: *Saprolegnia delicata*, once; *Saprolegnia* sp. (non-sexual form, with oddly-shaped gemmae), once; *Achlya pinnulata*, n. sp., three times; *Achlya* sp., once; *Aphanomyces* sp. (non-sexual), once; and *Dictyuchus sterile*, five times.

The following species appear to be endemic to localized areas in the San Bernardino Mountains or adjacent valleys in southern California: *Saprolegnia bernardensis*, n. sp., six times; *Saprolegnia delicata*, five times; *Saprolegnia* sp., six times; *Achlya caroliniana*, eight times, and *A. diffusa* n. sp., four times.

Achlya heteromorpha n. sp., female strain, has been taken twenty-nine times, mostly in and near the city of San Bernardino. It was obtained once in Death Valley, along with *Saprolegnia ferax*, *Dictyuchus sterile*, and *Aphanomyces* (a non-sexual form).

Achlya heteromorpha n. sp., male strain, was taken twice, at stations 200 miles apart, in southern California.

Dictyuchus sterile has been most abundant of all species distributed uniformly over all of California, eighty-nine times. A sexual strain of *Dictyuchus* has been isolated five times.

Other species occurring plentifully in the entire state include: *Saprolegnia ferax*, seventy-five times; *Saprolegnia delicata*, seventeen times; *Saprolegnia* sp. (non-sexual), two distinct forms described as new, eighty-six and seven times respectively; other species of *Saprolegnia*, unidentified, fourteen times; *Achlya pacifica*, n. sp., nine times; *A. pinnulata*, n. sp., five times; *A. californica*, n. sp., ten times; *A. sp.*, nineteen times, nine of these producing no sexual bodies; and *Aphanomyces* (a non-sexual strain), fifty-eight times.

A few species, less plentiful, include: *Aphanomyces balboensis*, n. sp.; *A. scaber*; *A. laevis*; *A. sp.*; *Leptolegnia* sp. (non-sexual); *Geolegnia inflata*; *G. septisporangia*; *Brevilegnia megasperma*; and *Calyptralegnia unisperma* var. *litoralis*. Species of *Olpidiopsis* (parasitic) have been taken three times.

RELATIONSHIP OF TOP GROWTH TO SUGAR BEET CROWN TEMPERATURES AND INDUCTION OF FLOWERING. *Eubanks Carsner and Bion Tolman, United States Department of Agriculture, Riverside, California.*—Initiation of the seed-stalk and flowering in sugar beets is brought about mainly by the cumulative effect of prolonged low temperature exposure followed or accompanied by the effect of long photoperiods. In a seed growing area it is impossible to control air temperatures during the overwintering period, but it is possible to modify soil temperatures and in a measure control the thermal environment of

the beet crowns. Modification of soil and crown temperatures is brought about mainly by control of foliar growth. Foliar growth is controlled by planting date, fertilizer practices and spacing of plants. In southern Utah, the development and maintenance of an extensive growth of leaves to shade the soil and help create the most effective temperature range for thermal induction proved to be beneficial.

THE RELATION OF TEMPERATURE TO REPRODUCTION IN SUGAR BEETS. *Myron Stout, United States Department of Agriculture, Riverside, California.*—The economic varieties of sugar beets are biennial plants which require the influence of cool temperatures, combined with or followed by long photoperiods to induce reproductive development. The relative extent of thermal induction during storage at different temperatures was measured by conducting bolting tests in a warm environment under long photoperiods. The beets bolted more rapidly and completely after storage at 6° to 8°C. than after storage at lower temperatures. There was little increase in the bolting tendency of beets as taken from the field in mid-winter, after storage at temperatures near 0°C. The bolting tendency of beets, which were taken from the field in mid-winter, was greatly reduced by a comparatively short period of storage at a temperature of 23° to 24°C. This indicates that the biochemical processes associated with thermal induction are reversible and that the rate of change is greatly influenced by temperature.

MALE STERILITY IN SUGAR BEETS PRODUCED BY COMPLEMENTARY EFFECTS OF CYTOPLASMIC AND MENDELIAN INHERITANCE. *F. V. Owen, United States Department of Agriculture, Riverside, California.*—The nature of the inheritance of male sterility in beets indicates two types of cytoplasm. Plants with N cytoplasm produce normal and abundant pollen. Plants with S cytoplasm may produce aborted pollen and become completely male sterile. The breeding evidence indicates that several Mendelian factors may influence pollen development when carried by plants with S cytoplasm, but the same factors have no effect when carried by plants with N cytoplasm. Most of the breeding behavior is explained by assuming that two Mendelian factors, *x* and *y*, have effects complementary to the influence of the S cytoplasm as follows:

$S\ x\ x\ z\ z$	Male sterile with white, empty anthers.
$S\ X\ x\ z\ z$	
$S\ x\ x\ Z\ z$	Semi-male sterile with yellow anthers but
$S\ X\ X\ z\ z$	little or no viable pollen.
$S\ x\ x\ Z\ Z$	
$S\ X\ x\ Z\ z$	More or less normal pollen depending upon
$S\ X\ X\ Z\ z$	favorable or unfavorable environmental
$S\ X\ x\ Z\ Z$	conditions, but the anthers sometimes fail
$S\ X\ X\ Z\ Z$	to open.

Crosses between male sterile ($S\ x\ x\ z\ z$) ♀ and normal ($N\ x\ x\ z\ z$) ♂ plants produced F_1 offspring, all of which were completely male sterile. Crosses between semi-male sterile ($S\ X\ x\ z\ z$) ♀ and normal ($N\ x\ x\ z\ z$) ♂ plants produced F_1 offspring,

approximately half of which were male sterile ($S\ x\ x\ z\ z$) and half semi-male sterile ($S\ X\ x\ z\ z$). Reciprocal combinations ($N\ x\ x\ z\ z\ \varnothing \times S\ X\ x\ z\ z\ \sigma$) sometimes made possible by the scant production of viable pollen on $S\ X\ x\ z\ z$ plants, produced F_1 offspring all of which bore completely normal and abundant pollen.

The unique nature of the inheritance of male sterility in sugar beets has facilitated the wholesale emasculation of plants for hybridization purposes.

COMPARATIVE INFLUENCE OF CLIMATE AND GRAZING ON RANGE PLANT COVER. *Selar S. Hutchings, Intermountain Forest and Range Experiment Station, Ogden, Utah.*—The comparative influence of climatic factors and those of grazing on plant cover and plant succession constitutes one of the most controversial questions in range management. Some individuals^{1,2} maintain that range deterioration and changes in plant cover result largely from fluctuations in climate. Others³ believe that climatic factors exert a marked influence on forage yields and plant succession but in the main they do not result in wholesale replacement of plant species. Comparisons of vegetation at eight locations in 1934, following a period of severe drought, and again in 1941, during a period of good precipitation, indicate that plant reaction to drought and precipitation results primarily in changes in production and loss of less tolerant plants. These may not be the more palatable plants, since shadscale and curlygrass, species of low palatability, suffered most from drought. Reduction in plant cover from overgrazing results in a differential loss of the more palatable forage plants. Heavy grazing reduces the plant vigor, thins the plant cover, prevents seedling reproduction, and makes possible the invasion of species low in palatability, including introduced annuals such as Russian thistle, which in some cases completely replaces native forage plants.

INFLUENCE OF TIME AND FREQUENCY OF GRAZING ON RANGE READINESS AND FORAGE PRODUCTION. *George Stewart, Intermountain Forest and Range Experiment Station, Ogden, Utah.*—Ranges on which grazing began early in spring, that is, soon after plant growth had started, have almost invariably deteriorated. Range administrators, therefore, deemed it necessary to prevent this early grazing which they came to designate as "premature" grazing. As more research was done, however, the causes and effects were found by no means to be as simple as the original evidence and conclusions seemed to warrant. In many cases early grazing

³ Stewart, George, W. P. Cottam, and Selar S. Hutchings. Influence of unrestricted grazing on northern salt desert plant associations in western Utah. Jour. Agric. Res. v. 60(5): 289-316, illus. 1940.

merely permitted another grazing to follow after a short interval. Frequency of grazing has proved in the long run to be a more potent cause of plant weakening than early grazing *per se*.

Early grazing is damaging, however, at least on mountainous ranges, since the ground is soft in early spring, and tramping by animals, therefore, tends to uproot plants, especially seedlings. The grazing of seedlings is in itself likely to be destructive to forage reproduction either by uprooting the young plants or by removing the shoots and leaves before the plant has become self-supporting. Early grazing does minor injury to established perennials provided they are not again grazed until maturity. Regrowth after early grazing is slow in cool weather, and repeated grazing reduces storage of food-reserves, thereby weakening the plants. Forage during its early growth is chemically rich but low in total yield, which may make the grazing capacity small for some weeks.

SOME EDAPHIC AND CLIMATIC RELATIONSHIPS IN PLANT SUCCESSION AND HABITAT BALANCE. L. A. Stoddart and A. D. Smith, *Utah State Agricultural College, Logan, Utah*.—Soil forming processes acting upon rock materials make, in early development, an increasingly productive soil in terms of quantity and, also diversity of plant species produced. Productivity may increase until the soil and its biome reach a point of relative stability with the climate. The nature and, hence, productivity of soil at this "climax" point is determined by climate. The parallelism and interdependence existing between soil development and normal plant succession is of great importance to the ecologist, although too often it is overlooked. Soil plays a varying rôle as a determinant or limiting factor to plant production—both volume and species composition. In this rôle it alternates somewhat with climate as succession progresses or regresses. Different climates induce different relationships.

Through successional development, the biome and the soil attain a balance with the climate as marked by a virtual cessation of trends. The biotic and edaphic "climax" can be said to have been reached. Further changes are oscillatory or cyclic and result from fluctuating weather conditions and temporary predominance of competing members of the climax vegetation. Apparently, either the soil or the climate may be the direct factor determining the point of relative stability of vegetation.

POST-PLEISTOCENE VEGETATION AND CLIMATE OF THE PACIFIC NORTHWEST. Henry P. Hansen, *Oregon State College, Corvallis, Oregon*.—A preliminary study of post-Pleistocene forest succession in the Pacific Northwest has been made by pollen analyses of peat bogs and lake sediments. In the Puget Lowland of Washington, the climax forests are composed of western hemlock (*Tsuga heterophylla*) and western red cedar (*Thuja plicata*), with Douglas fir (*Pseudotsuga taxifolia*) persisting in predominance as a result of recurring fire. The pioneer postglacial

forests consisted chiefly of lodgepole pine (*Pinus contorta*), which was replaced by Douglas fir, and which in turn was partially replaced by western hemlock.

On the Oregon Coast, the climax forest consists of western hemlock and Sitka spruce (*Picea sitchensis*). The post-Pleistocene forests have consisted of these species in about equal abundance. In the Willamette Valley of Oregon, the principal tree species are Douglas fir and Oregon white oak (*Quercus garryana*). The initial post-Pleistocene forests were composed of lodgepole pine, Sitka spruce, and lowland white fir (*Abies grandis*). These were slowly replaced by Douglas fir, which in turn was replaced by oak in comparatively recent time. On the east slope of the central Cascades of Oregon, the climax forests are composed of lodgepole and western yellow pine (*Pinus ponderosa*). The former persists as an edaphic climax because of an extensive pumice mantle deposited by post-Pleistocene volcanic eruptions. One of these was the eruption of Mount Mazama that formed Crater Lake, about 5,000 years ago. The pollen record of bogs in this region shows several trends toward yellow pine predominance, which were interrupted by the deposition of pumice, but lodgepole apparently has been predominant since the first major eruption.

In northern Idaho the climax forests consist of western hemlock, western red cedar, and lowland white fir, with western white pine (*Pinus monticola*) persisting as a subclimax due to recurring fire. The pioneer post-glacial forests consisted principally of lodgepole and white pine. The former was superseded by white pine, which remained predominant during the rest of the post-Pleistocene. A definite trend toward a climax forest occurred in recent time, but it was apparently interrupted by fire. In northeastern Washington, the climax forest is composed largely of yellow pine. The pioneer post-glacial forests consisted of lodgepole and white pine, and western larch (*Larix occidentalis*). These were succeeded by chenopods, grasses, and composites, suggesting a hot, dry period. These were slowly replaced by yellow pine, which has persisted to the present.

In north central Washington, the climax forests are composed of yellow pine, Douglas fir, and western larch. The initial post-glacial forests were composed of lodgepole, white, and yellow pine, with the first predominant. Yellow pine gradually assumed predominance during the post-Pleistocene, with some Douglas fir in more recent time. East central Washington is covered with the bunchgrass prairie and sagebrush and its associates. A peat profile in this region shows that grass has been predominant during most of the post-Pleistocene. Trees recorded in significant proportions are lodgepole, white, and yellow pine, although the nearest present-day forests are thirty miles away. Chenopods and composites are also recorded abundantly throughout. The post-Pleistocene general climatic trend has apparently been one of warming and drying to a maxi-

mum, followed by cooling and a slight increase in moisture to a degree which has persisted to the present.

EFFECT OF NUTRITION ON VACUOLAR COMPONENTS. *Howard S. Reed, University of California, Berkeley, California.*—Cellular inclusions have for over a century received attention from plant cytologists, and they have generally agreed that colloids of one sort or another are present in plant cell vacuoles. Recent studies show that these materials have great significance in the activity of the cell and are intimately related to health and disease. A characteristic type of spherical inclusion, consisting of catechol, has formerly been mistaken for micro-organisms in the cell. The present work describes how these bodies are formed in the vacuolar solution by a separation of phases. These globules consist of catechol enveloped in a layer of phospholipoid. The coacervated aggregates have been found in the vacuoles of hypoplastic cells of leaves, in the post-meristematic cells of growing shoots of apricot trees suffering from little-leaf, as well as in the roots of orange seedlings growing in zinc-deficient nutrient solutions. The globules of this type have never been observed in the cells of healthy plants.

THE ZINC CONTENT OF "LITTLE-LEAF" AND NORMAL LEAVES. *Elmer Archibald and F. B. Wann, Utah State Agricultural College, Logan, Utah.*—In the State of Utah a serious "little-leaf" condition has been observed on fruit trees in local areas of Utah, Davis, and Boxelder Counties. Since the application of zinc to the plants corrects the condition, it is probable that the "little-leaf" is due to a zinc deficiency. Zinc sulphate applied as a foliage spray has given good control. Chemical analyses for zinc in diseased and normal leaves of peach, cherry, apple, and plum showed: (a) little or no transverse movement of zinc in the plant; (b) higher zinc content in leaves from trees sprayed with zinc sulphate than in leaves from trees treated by other control methods. Addition of zinc to the soil did not increase the zinc content of leaves. (c) Trees with less than 123 micrograms of zinc per gram of dry matter showed little-leaf symptoms; healthy leaves contained from 123 to 345 micrograms of zinc per gram of dry matter.

WHICH FACTORS LIMIT THE GROWTH OF TOMATO PLANTS? *F. W. Went, California Institute of Technology, Pasadena.*—By growing tomatoes in air-conditioned greenhouses reproducible results on tomato growth were obtained.

So far it has not been possible to increase the growth rate of plants 50–100 cm. tall beyond 30 mm./day. At that rate none of the known plant hormones limit growth. Growth can be increased neither by a change in the nutrient solution, nor by increased aeration of the roots, nor by higher temperatures, nor by more light, nor by different photoperiods, nor by other air humidities nor by changed feeding schedules. Under sub-optimal conditions the water supply or the nutrient supply or the wrong photoperiod or auxin or the caulocaline production can

each be limiting. It was found, however, that under optimal conditions the sugar supply towards the growing point is limiting. Experiments under different temperature conditions suggest that it is the sugar transport rather than photosynthesis which is the bottleneck in tomato stem growth, just as it seems to be for fruit growth.

THE ORIGIN OF THE WESTERN SPECIES OF DRABA. *C. Leo Hitchcock, University of Washington, Seattle, Washington.*—*Draba*, a genus of the Mustard family, is predominantly a plant of arctic or montane habitat. Several of the perennial species apparently moved southward in western North America with the invasion of the ice sheets and were quite widespread in range at one time. At the present time most of these species are "stranded" on the higher peaks of the Rocky, Cascade, and Sierra Nevada Mountains.

Subsequent to the ice ages, variation in these and isolated populations has resulted, in many instances, in the formation of several closely related, but genetically different specific, or subspecific entities. In some species, however, no such noticeable variation has occurred, relict populations of circumpolar species persisting as far south as Colorado.

The discussion will be concerned with the possible origin of most of the montane species of the genus as it occurs in western United States.

ORIGIN AND AFFINITIES OF THE FLORA OF CENTRAL ROCKY MOUNTAINS. *Joseph Ewan, University of Colorado, Boulder, Colorado.*—Five sources may be recognized for the region: (a) *holarctic*, the largest and most prominent element, of which the boreal floras are almost entirely composed, and which even extends down and outwards from cordillera to plains adjacent; (b) *southeastern*, small but distinctive group, remotely of Mexican origin but entering our region through the lower Mississippi Valley; (c) *southwestern*, second largest element, remotely of Mexican origin but by way of (?) secondary centers most immediately related to present Arizona-New Mexican floras; (d) *Pacific*, small but characteristic element, possibly entering via the Columbia River catchment basin; (e) *endemic*, weak group, the components related either to holarctic or southwestern elements. Criteria for determination of the past movements of any given group are: (a) present greatest concentrations of species; (b) comparative morphology of peripheral members of the group against that of members of concentration centers; (c) distribution of endemic species of the group with relation to its periphery; (d) comparative data from cytogenetics (where available) as to derivative chromosomal types with reference to parental diploid species. The fact that all groups of vascular plants from Pteridophyta to the most highly evolved Sympetalae exhibit this past migration and have participated in it lends support to the belief that there must have been pre-Pleistocene movements of this flora.

TAXONOMIC-ECOLOGICAL RELATIONSHIPS OF THE GENUS ZIGADENUS. *O. S. Walsh, Montana State College, Bozeman, Montana.*—The spelling *Zigadenus*

is adopted to conform to the original spelling used by Michaux when the generic name was first published.

The species of *Zigadenus* are highly polymorphic, exhibiting many growth forms as expressions of adaptability to environmental conditions. Kind and availability of soil moisture are apparently the major factors controlling distribution and causing greatest variation in growth habit in many species.

Experimental plants confirmed certain observed growth habit tendencies as environmental adaptations common to all species. Clusters of plants, often large and with numerous sheathing basal leaves and some suffrutescence, characterize growth in moist areas. Slender, sparse plants widely separated occur mostly on rocky or dry areas. Alkalinity reduces height growth but induces larger or heavier succulent foliar growth and large bulbs. Progressive dwarfing appears in all montane species near the upper limits of their altitudinal range, and modifies other growth tendencies. Many previously named "species" have been based on these habitat variations.

Proposal is made to retain sixteen species as valid and reduce four additional "species" to sub-specific rank. Most other previously named species are considered to be "formae" or environmental adaptations only. Names for these habitat forms are not recommended.

NOTEWORTHY PLANTS OF NORTHEASTERN NEVADA. A. H. Holmgren, *Utah State Agricultural College, Logan*.—A study of the flora of northeastern Nevada has resulted in several interesting discoveries. The following list includes new records for the state, and range extensions within the state. The asterisk denotes which are apparently hitherto unreported for the state.

Botrychium Lunaria (L.) Swartz var. *minganense* (Vieill.) Dole; **Selaginella selaginoides* (L.) Link; *Najas marina* L.; **Triglochin palustris* L.; **Lilaea subulata* H. B. K.; **Damasonium californicum* Torr.; **Glyceria occidentalis* (Piper) J. C. Nels.; **Poa arctica* R. Br.; **Eragrostis hypnoides* (Lam.) B. S. P.; **Triodia pilosa* (Buckl.) Merr.; **Blepharidachne Kingii* (S. Wats.) Hack.; **Agrostis humilis* Vasey; **Hierochloa odorata* (L.) Beauv.; **Carex brunnescens* (Pers.) Poir.; **Carex filifolia* Nutt.; **Carex limosa* L.; **Juncus articulatus* L.; **Luzula spicata* Desv.; **Corallorrhiza striata* Lindl.; *Salix Lemmoni* Bebb; *Eriogonum chrysocephalum* A. Gray subsp. *desertorum* Maguire; *Halogeton glomeratus* (Bieb.) Mey.; *Arenaria Franklinii* Dougl.; **Nymphaea odorata* Ait.; **Ranunculus testiculatus* Crantz; *Aquilegia caerulea* James; *Lepidium nanum* S. Wats.; *Draba Douglasii* A. Gray; *Trifolium monanthum* A. Gray; *Linum Kingii* S. Wats. var. *sedoides* Porter; **Viola bellidifolia* Greene subsp. *valida* Baker; **Epilobium lineare* Muhl.; **Eryn-*

gium alismaefolium Greene; **Lomatium montanum* C. & R.; **Gratiola neglecta* Torr.; *Galium Matthewsii* A. Gray; **Aplopappus lanuginosus* A. Gray subsp. *Andersoni* (Rydb.) Hall; *Erigeron Austiniae* Greene; *Erigeron compactus* Blake; *Stylocline micropoides* A. Gray; **Stylocline filaginea* A. Gray; *Wyethia helianthoides* Nutt.; *Eatonella nivea* (D. C.) Eat. A. Gray; *Tanacetum potentilloides* A. Gray.

THREE NATURAL HYBRIDS OF THE COMPOSITAE IN WYETHIA AND BALSAMORHIZA. Bassett Maguire, *Utah State Agricultural College, Logan*.—Three putative natural inter-specific hybrids in *Wyethia* and *Balsamorhiza* are reported. Evidence of field association and of comparative morphological study are offered in support of these propositions.

In numerous areas in Idaho *W. amplexicaulis* Nutt. and *W. helianthoides* Nutt. occur growing intimately together. In such instances approximately 15 per cent of the mixed population show intermediacy of the essential morphological characters. Evidence seems to indicate that these intermediate plants are natural hybrids and are fertile, and that they may back cross with either parent. On no occasion where both species were not present, did plants of intermediate character occur. The putative hybrid *W. amplexicaulis* × *helianthoides* had previously been described as *W. Cusickii* Piper.

A somewhat comparable but more complex situation was observed to take place in *Balsamorhiza* in northeastern Nevada, involving *B. sagittata* as one probable parent, and either or both of two forms which had earlier been interpreted as phases of *B. hirsuta*, as the other probable parent. One of these forms seems to be a minor variant of *B. hispidula*, which entity appears to be no more than a geographical segregate of the more northern *B. hirsuta*. The other, differing from the first in distressingly little beside character of pubescence, is, however, similar to specimens designated by Sharp as *B. platylepis*, plants which seem to be too close to *B. Hookeri* for specific distinction. Both of these forms occur on thin stony soil, sometimes intermixed, while in the same region *B. sagittata* occupies more favorable deeper soil. Where the area of either or both of the two populations becomes contiguous with that of *B. sagittata* invariably morphologically intermediate plants occur in the ecotone between them. These intermediate plants have been designated as putative hybrids between *B. sagittata* and *B. platylepis* (? a ssp. of *B. Hookeri*) on the one hand, and between *B. sagittata* and *B. hispidula*, var. (? a ssp. of *B. hirsuta*) on the other.

Transplants of all forms of both genera concerned were found to be easily made. Attempted germination of seed was not successful. These materials are suggested as offering excellent opportunity for cytogenetical and experimental taxonomic study.

STRUCTURE AND GROWTH OF THE VEGETATIVE SHOOT APEX OF *GARRYA ELLIPTICA* DOUGL.¹

Roger M. Reeve

THE RESEARCHES of Grégoire (1935a and b, 1938) and Louis (1935) have brought attention to a number of the neglected problems of foliar and floral histogenesis. Grégoire (1935b) rejected the classical interpretation of the flower and insisted that no homologies exist between vegetative and floral apices. Louis, in detailed comparative studies of a number of species, has shown the interrelationship of shoot and lateral organs from the earliest stages in ontogeny of the primordia up to and including stages of early vasculature. The significance of these contributions, and the studies of earlier workers, as related to phylogenetic interpretations of the vegetative shoot and the flower, have been reviewed by Foster (1936, 1939, 1941).

Zimmerman (1939) has correlated evolution and ontogeny in a broad concept which he terms "hologeny." In this very interesting theoretical treatment the evolution and the ontogeny of plant organs are projected into a time and space relationship descriptive of the evolution and developmental history of the entire organism. In the writer's opinion, further detailed histological studies conducted in an objective manner can only lend support to such a viewpoint. Unfortunately, many phylogenetic interpretations have been based upon incomplete information on organ histogenesis, and, as yet, the stages of transition from vegetative apices to floral apices have been neglected.

The present study on the apices of *Garrya* was undertaken in an effort to contribute further information related to these problems. The genus was chosen because the different sorts of apices were readily obtainable on the same plants throughout the year near Berkeley, and because the decussate phyllotaxis facilitated interpretation of serial sections. There have been few detailed studies made of the apices of woody, amentiferous species. These observations on the vegetative shoot will be followed with comparative studies on catkin ontogeny.

The author is indebted to Professor A. S. Foster, under whom this study was undertaken, for aid and encouragement during the progress of the research. Appreciation is also accorded to Professor Katherine Esau for kindly criticism and suggestions.

TAXONOMY AND GENERAL ORGANOGRAPHY.—The Garryaceae consists of the single genus *Garrya* and has been variously placed in systems of classification. Prevalent among the ideas of its affinity is either that it is closely related to or is included with the Cornaceae. Baillon (1877a and b) and Hallock (1930) have discussed the opinions of the various systematists and are in general agreement with those who place the Garryaceae in the Umbellales. There

is no intention in this paper to advance further suggestions concerning the phylogeny of the family. It is significant, however, that morphogenetic investigations have been made upon relatively few members of the Umbellales.

Floristically, *Garrya* is an old genus belonging to the Mexican Plateau element. It has been found in the Miocene, and once must have been more widely distributed than at present. Present distribution is local, ranging from Oregon into Central America and the West Indies. In California there are three or four fairly distinct species between which occur intermediate forms strongly suggesting hybridization at a time when the genus was more general in distribution.

The growth habit is more or less uniform throughout the genus, varying from woody, dioecious shrubs to diffusely branched, tree-like forms. The buds are protected by a series of acute cataphylls which are clothed with dense, sclerotic epidermal hairs in most of the California forms. The cataphylls are formed during a period of retarded growth when the foliage buds and catkins become distinguished from each other by slow elongation of the catkins from early summer throughout the fall. Not infrequently the latest formed of these cataphylls become quite leaf-like just as the foliage bud resumes production of foliage leaf primordia in the mid-winter weeks. Buds develop in the axils of foliage leaves and in the axils of many of the transition cataphylls, whereas usually only rudimentary primordia are found in the axils of the cataphylls.

The activity responsible for foliage leaf production merges into shoot elongation and extends over a period from January to early summer. It is particularly interesting that the various stages of shoot and catkin development may not be at all comparable, at any given time, between plants separated only a few miles. Such differences are directly related to peculiar, localized climatic conditions so characteristic of the Pacific coast. Most forms, however, show transition cataphylls at the tips of some of their shoots as the season of active growth ends (Plate II, fig. 3).

The catkins are borne terminally in clusters and range from two to eight or more inches in length when fully expanded. Catkins are frequently found in the axils of both the lower catkin cataphylls and some of the transition cataphylls below a catkin cluster, thus forming a compound ament.

TECHNIQUE.—A total of several hundred buds of *G. elliptica* was collected at weekly intervals for eighteen months. Several collections of *G. buxifolia*, *G. Congdoni*, and *G. Fremontii* were made for comparative studies. The tightly overlapping cataphylls with their dense sclerotic tomentum necessitated

¹ Received for publication June 2, 1942.

Note the slight elongation of rib-meristem in the region of the oldest node.—Fig. 2. Longisection of shoot apex during cataphyll formation (January 23, 1940). $\times 77$. Note the compacted rib-meristem units and the absence of axillary bud primordia. The rectangle is the area shown in figure 11.—Fig. 3. Longisection of catkin apex showing axillary floret branch primordia of \varnothing florets. Note narrow pith region of axis. $\times 77$.—Fig. 4. Median longisection of the apical dome (of fig. 1) showing early medulation within the apex. $\times 266$. PS—provascular cells.—Fig. 5. Median longisection of shoot apex showing emerged primordia (March 23, 1940). $\times 225$. PS—provascular cells. This apex is cut at a right

careful dissection in order to insure adequate penetration of the killing agents. Formalin acetic acid (or propionic acid) and 70 per cent alcohol in a 5:7:88 ratio and Karpechenko's solution were used as killing agents. All material was aspirated as soon as possible in the reagent for at least an hour. Aspiration was repeated for an hour in the 55°C. paraffin oven after the material had been run up into pure paraffin (cf. Ball, 1941a). The dehydration and paraffin infiltration described by Ball (1941a) was employed.

Prior to cutting, the imbedded material was trimmed to expose a small portion of the base of the bud, and then submerged in distilled water and soaked for two to four days at room temperature, or four to six hours in a 37° oven. This treatment decreased the static generated by the microtome, and also softened the harder tissues sufficiently to diminish tearing appreciably. Longitudinal, transverse, and bias sections parallel to the diverging leaf traces were cut at 4 μ and 6 μ . Tannic acid and iron chloride in combination with safranin produced the most photogenic staining of a number of schedules employed (Foster, 1934).

The cell line drawings were produced by tracing photomicrographs with India ink and then bleaching the photograph in IKI, followed with hypo then water, as described in various photography manuals.

ORGANIZATION AND GROWTH OF THE VEGETATIVE SHOOT APEX.—Apices of fully developed buds vary in diameter at the base of the apical dome from 120 μ to 180 μ . The apices of young lateral buds, in which the early cataphylls are still embryonic, are of smaller diameters. The level of this measurement is not intended to be used as a boundary delimiting the apex. Reference to the apex of *Garrya* may be considered as applying to that distal portion of the shoot on which the youngest pair of primordia has been formed (Plate I, fig. 1, 2, and 3).

In all species examined, the apical dome has a one-layered tunica and an underlying corpus (Plate I, fig. 7 and 8). At certain stages of development it may appear that the tunica is two or even three cell layers deep (Plate I, fig. 4 and 5). Careful examination shows, however, that even during the period of cataphyll formation there are periclinal divisions in the subsurface layer at the summit of the apical dome (Plate I, fig. 7). During the active growing season, the subsurface cells at this region lack consistent uniformity of size and arrangement characteristic of a tunica. Although periclinal divisions are not frequent in this region, they, as well as divisions in variable planes, do occur.

There is a distinct stratified appearance in the corpus following emergence of the most recently initiated primordia (Plate I, fig. 4 and 5). This strati-

fication appears to be correlated with the shifting of activity from the apical dome to the primordia when the apex is in a minimal area stage. Sections cut median to emerging primordia show a decided stratification in the corpus (Plate I, fig. 5). Such stratification is less pronounced in sections median to the next primordia to be produced (Plate I, fig. 4). Before emergence of these primordia, and during the lateral expansion which produces their bases, the cells of the subsurface layer at the summit of the apical dome lack uniformity of size and alignment; both oblique and periclinal divisions may take place.

Variation in tunica stratification has been reported by Boke (1940) for *Acacia*, by Cross (1937, 1938, 1941) for *Fiburnum* and *Vinca*, by Foster (1935a) for *Carya*, and by Schmidt (1924) for *Scrophularia*, and is known to occur in other genera. Cross (1941, 1942) concluded that a variation in the uniseriate tunica of several genera of Gymnosperms constitutes a developmental series which may illustrate the evolution of the tunica as resulting from a reduction of periclinal divisions in the surface layer. Although in these Gymnosperms, the surface layer shows considerable variation, information was not included regarding the relationship of that variability to the periodicity of organ formation, or to seasons of growth.

Foster (1938, 1939, 1941) in his reviews of the problems of shoot growth has pointed out the danger of formalizing Schmidt's (1924) tunica-corpus concept. Although there may be some phylogenetic significance in the occurrence of a multiseriate tunica, the variable stratification in apices on a single plant, as found in *Garrya*, *Acacia*, and other genera, surely indicates a more immediate relationship to shoot growth and organ initiation.

The origin of the tunica in *Garrya* was not determined. Longisections of nearly "mature" embryos constituted the youngest material examined. At this stage the young sporophyte possesses a well-defined surface layer continuous with the uniseriate tunica of the epicotyl apex. The corpus is composed of only a few undifferentiated cells forming a zone about 40 μ to 50 μ in diameter and having the shape of a bi-convex disc (Plate I, fig. 8).

In the summit area of the corpus in a fully-developed apex a central zone of cells may be distinguished as the mother cells of the corpus. Cells flanking and below this zone converge toward it in short, irregular rows of common origin (Plate I, fig. 4 and 5).² The immediate derivatives of the central

² In descriptions of confocal apices most authors speak of cells as "diverging" from a central zone. This viewpoint may have arisen from the classical concept of the apical cell and its "diverging" segments. Since the general direction of shoot differentiation is acropetal, the present writer prefers the term used.

angle plane to that shown in figure 4.—Fig. 6. Longisection of apical flank showing a leaf primordium in an early stage of evagination (March 23, 1940). $\times 290$. Oil immersion magnification of the medulation zone of the apex in figure 2. $\times 500$. Note the pronounced primary pit fields (arrows).

Plate II. Fig. 1-7.—Fig. 1 and 2. Longi-diagrams of shoot apices shown in figures 1 and 2, respectively, in Plate I. *T*—tunica, *C*—corpus, *MV*—approximately the upper limit of medulation, *PS*—provascular strands, *SZ*—shell zone or initials of axillary bud, *B*—base of primordium immediately below and decussate to those shown in the diagrams (this is approximately through the point at which the lateral wings of the primordia unite), *AP*—axillary bud primordium, *Ca*—cataphyll primordium. Small, solid arrows indicate the direction of growth in the corpus. The small, double arrows indicate regions of periclinal divisions which initiate primordia. Broken arrows indicate the cell lineages of rib-meristem.—Fig. 3. Schematic representation of the seasonal production of lateral organs on the shoot. *f*—floret, *C*₁—catkin cataphylls, *T*—transition form, *B*—terminal bud, *C*—cataphyll of vegetative shoot, *a*—axillary bud, *F*—foliage leaf.—Fig. 4-7. Transverse diagrams of figures 3, 4, 5 and 6, respectively, in Plate III. *PR*—provascular ring, *d*—cambial-like divisions of the adaxial and abaxial meristems. The provascular traces are labeled “*M*” for median and “*L*” for lateral, and the numbers correspond to the paired primordia in the order of their ages (thus, primordia I is the youngest).

zone of mother cells are designated in Plate II, figures 1 and 2, by single, solid arrows. This zone forms the precursors of the rib-meristem and the lateral meristem of the corpus from which primordia arise. The more active portion of the corpus is lateral in position (Plate I, fig. 4 and 7). The short, double arrows in figures 1 and 2, Plate II, designate the regions of leaf initiation where periclinal divisions are most abundant. In the immediate vicinity of this region, and differentiating slightly below it, the provascular cells first appear within the apical dome (Plate I, fig. 4, 5, 6; Plate II, fig. 1 and 2). These youngest provascular cells are continuously connected with, and differentiated upward from, older provascular tissue lower in the axis. As such differentiation invades the apical dome it occurs lateral to leaf gap areas of ground meristem, and then the strands of provascular cells converge and "fuse" above the leaf gaps. This provascular tissue may be compared to the tissue described by Louis (1935) as "prodesmogen"; however, its cells are already definitely elongated. The differentiation of this early stage of provascular tissue will be discussed later with reference to the vasculature of primordia.

In Plate II, figures 1 and 2, the dotted line "M-V" presents an approximate division between the more densely staining corpus cells and the region of early medulation or vacuolated rib-meristem (see also Plate I, fig. 4 and 5). The relative extent of these two regions, and the general shape of the apical dome are evidently determined by the amount of mitotic activity and by the particular stage in development of the most recent organs (Plate I, fig. 4 and 5).

Considerable growth takes place in the rib-meristem (Plate I, fig. 9 and 10). At a level two or three nodes below the apical dome highly vacuolated rib-meristem is found; and nearly up to this level, where occasional mitotic figures may still be found, there are large druses occupying nearly the entire volumes of some cells. In the diagrams (Plate II, fig. 2 and 3) the rib-meristem is indicated by the broken arrows. Other characteristics of this tissue are: thickened primary wall areas, primary pit fields, and intra-cellular substance—features similar to those described by Boke (1940, 1941) and Foster (1938, 1939, 1941) for similar meristem.³ These wall characteristics may be observed in the apices of cataphyllary buds at the level of the youngest node (Plate I, fig. 2 and 11), but above that region they are less pronounced. In *Ginkgo*, Foster (1938) has described and illustrated these features within the central mother cell group of the apical dome.

Although the cataphylls and the terminal apex of the catkin are essentially vegetative in nature, catkin ontogeny will be discussed in a later paper. During early stages of development, the organization of the

apical dome of the catkin is the same as that described for the apex of the leafy shoot. The ontogeny of the cataphylls on both catkin and leafy shoot is discussed in the following paragraphs.

ONTOGENY AND VASCULATION OF CATAPHYLL AND FOLIAGE LEAF PRIMORDIA.—These organs are histologically similar during the early stages of their formation, but their initiation and different rates of development are correlated with growth conditions specific to the apices producing them. Retarded shoot growth and retarded activity of the apex are concurrent with cataphyll production. In general, foliage leaf primordia that are still embryonic are longer than cataphyll primordia that have undergone considerable internal differentiation. This difference is evident in primordia between 50 μ and 100 μ long (Plate I, fig. 1, 2, and 3). Provascular differentiation is more rapid in cataphyll primordia than in foliage leaf primordia of corresponding sizes, particularly in later stages of development.

Schüepf (1916) adopted Askenasy's (1880) term "plastochron" to designate the time interval between the formation of two successive sets of primordia in decussate species, or two successive primordia in species with alternate leaves. In this concept the plastochron is associated with the alternation of maximal and minimal areas of the apex (described by Schmidt, 1924). During one plastochron the apex passes from a minimal area into the next maximal area.

In *Garrya* the lateral periclinal lines in the corpus initiating a primordium and marking the end of a plastochron do not add appreciably to the area of the apex (Plate I, fig. 7). If formation of primordia is rapid, then the next pair are appearing as initials in the corpus while the immediately preceding pair evaginate.

According to Louis (1935), the maximal area of the apex is a result of the development of a "sous-bassement" (foliar buttress). In other words, the lateral expansions of the apex result in the formation of new primordia. Further activity within the foliar buttress leads to the upward and outward growth of the primordium.

Two stages of foliage leaf formation are shown in Plate I, figures 5 and 6, and Plate IV, figures 2 and 3. Plate I, figure 7, and Plate IV, figure 1, show the subsurface initials from which a cataphyll will develop. Periclinal divisions beneath the subsurface layer along the upper portion of the buttress initiate the apical meristem of the primordium (Plate I, fig. 5 and 6; Plate IV, fig. 2 and 3).

In stages immediately following the emergence of the primordium, the activity of its apical meristem rapidly extends the primordium into an upper portion histologically distinguishable from the lower portion in longisectional view. The upper third remains more or less undifferentiated (Plate I, fig. 1) in all cells beneath the protoderm until the primordium has reached an age comparable to that of primordia at the fourth node. The lower two-thirds be-

³ The term "meristem" is applied here in the more recent concept rather than in the classical sense by which meristematic cells were defined as being unvacuolated and undifferentiated.

comes progressively more differentiated from the base and insertion of the primordium toward its upper portion. The abaxial and adaxial sides contain vacuolating cells underlying the protoderm and surrounding the vascular strands. In the lower portion of a primordium at this stage of development, Louis (1935) distinguished an abaxial zone of "dorsal parenchyma" and an adaxial zone of "ventral parenchyma," and a central and apically extending "prodesmogen." The "prodesmogen" could well be termed "provascular meristem" in *Garrya* because it is composed of elongated cells and is continuous with the provascular tissue of the axis (Plate I, fig. 5 and 6; Plate IV, fig. 2 and 3). In fact, in *Garrya*, the elongation of the provascular cells occurs even before the abaxial and adaxial zones are clearly defined, and is shown in Plate IV, figure 3, as extending to the apical meristem of the primordium.

Louis (1935) assumed that the procambium differentiated basipetally into the axis and acropetally into the "prodesmogen" of the leaf primordium of *Lonicera*. Grégoire (1938) emphasized that, in contrast to the basipetal differentiation of procambium strands in primordia of foliage shoot apices, the procambium strands of the floral apex and its receptacular tissue differentiate acropetally and without relation to initiation of floral organs. The provascular cells of the foliage shoot apex of *Garrya* do not show a two-way differentiation, since they are continuous with older provascular cells lower in the axis. Moreover, as will be discussed in a later paper, the early differentiation of provascular cells in the axillary floret branch primordia is the same as that found in the early development of the axillary vegetative shoot. In both the differentiation appears to be acropetal.

Boke (1940, 1941) was unable to find any evidence of basipetal differentiation from a "procambial arc" in the phyllode primordia of *Acacia*, and concluded that the provascular differentiation in certain species of cacti is acropetal. Cross (1942) interpreted the differentiation of procambium in *Cunninghamia* as acropetal. To the writer's knowledge, relatively few attempts have been made to study the direction of differentiation of the first-appearing provascular cells in bias longisections cut tangential to the flanks of the apical dome. Schmidt (1924), Louis (1935) and others, however, have recognized that leaf traces are continuous laterally around the "leaf gaps" of the older primordia, but the leaf gap origin as associated with the initiation and earliest vasculature of a primordium has not been demonstrated. In this study, bias longisections proved to be very useful for determining the directional growth of provascular cells. It was also possible to establish that the traces to initiating primordia arise from older provascular cells very near the apical dome.

About 10μ below the level shown in figure 2. Note the early medulation in young axis.

At the beginning of a plastochron certain cells adjacent to the base of the emerging primordium can be distinguished in longisections as the first provascular cells in that region. They continue to elongate as the primordium develops (Plate I, fig. 5 and 6; Plate IV, fig. 2 and 3). As previously mentioned, the first provascular cells within the apical dome may be seen flanking the rib-meristem and extending to the approximate region from which the next pair of primordia will arise (Plate I, fig. 4). Radial and periclinal divisions in this provascular meristem further differentiate it from the ground meristem as the cells of the latter enlarge and become more vacuolate. In serial transverse and longisections, the provascular tissue may be traced through successively older nodes and internodes from its most distal extension downward into the axis without interruption.

This tissue, the future vascular tissue, has been described by Helm (1932) as the "meristem ring." Kaplan (1937) spoke of it, and similarly appearing cells lying between the provascular strands in the axis, as "Rest meristem." The present writer prefers the term "provascular ring," or simply "provascular meristem," because the entire meristem partakes in the formation of the vascular system of the axis. The less differentiated cells within this ring are potential provascular tissue since the interfascicular cambium arises from them. These are less elongated in the early stages of the nodal differentiation and form the parenchyma tissue of the leaf and branch gaps. During initiation of new traces some of the less elongated provascular cells near the apical dome become differentiated as branches from already defined traces of young primordia. These branches differentiate acropetally from their origins and unite to form traces to emerging primordia. Very near the apical dome the provascular cells differentiating into the youngest primordia are at stages of development comparable to the less differentiated cells within the provascular ring of the axis.

Longisections of *Garrya* buds cut tangential to the provascular ring at the base of the apical dome show the cells of well-defined traces as well as younger, less elongated cells (Plate V, fig. 1 and 2). The younger cells may be traced in serial sections to the regions of emerging primordia. Their appearance and differentiation within the provascular meristem proceed acropetally (compare Plate V, fig. 1 and 2, with Plate I, fig. 4, 5, and 6).

In Plate V, figure 2, the provascular cells indicated by the joined arrows lie in the position of a median trace to a member of the next pair of primordia decussate to the one illustrated. Examination of serial sections of this region showed that the provascular cells indicated by the single arrow belong to the edge of the median trace to the primordium illustrated. In other sections additional provascular cells occupy the region of the lateral traces to the

same primordium, and from one of these barely differentiated lateral traces a line of provascular cells diverges toward those indicated by the joined arrows. Thus, before establishment of discrete provascular strands, the origin and location of the future traces of a primordium are already evident within the ring of provascular meristem in and near the apical dome. Further differentiation of these provascular cells and of the traces they form proceeds

acropetally from the ring into the primordia. At the same time, the acropetal differentiation of additional provascular meristem takes place within the ring.

Nodal anatomy.—To illustrate further the relationship of the provascular tissue it is well to consider some of the features of the nodal anatomy of the bud. The organization and the general features of the vascular meristem of cataphyllary buds and of buds producing foliage leaves are similar. The

differences in the rates of tissue differentiation and maturation, as previously mentioned, are related to the seasons of cataphyll and foliage leaf production.

Proceeding acropetally through transverse serial sections from a region five or six nodes below the apex, the course of the provascular traces may be followed from the provascular ring of the axis into the primordia. At the level of insertion of the fourth oldest pair of primordia (*i.e.*, primordia IV), and in the internodal region below them, twelve distinct traces are present (Plate II, fig. 7; Plate III, fig. 6). The inner six of these are the traces of the third oldest pair of primordia (primordia III); the outer six belong to primordia IV. In figure 7, Plate II, the dotted ring "PR" represents the provascular tissue within which the traces to future primordia differentiate. In the diagrams of transverse sections in Plate II, the traces to the younger primordia (M-1, M-2, and L-2) contain cells that are only slightly elongated and are only slightly more differentiated than the provascular cells shown in figures 5 and 6, Plate I. As described by Louis (1935), the cell vacuolation of the central core and of the cortical regions of the axis delimits the ring of "prodesmogen" near the apex. This stage is illustrated in *Garrya* in figure 12, Plate III; however, here the cortical regions show only slight vacuolation and the provascular cells are somewhat elongated (see also Plate I, fig. 4, 5, and 6).

At the level where the inner six provascular traces enter the bases of primordia III, the median traces "M-2" to primordia II are visible and are continuous into the bases of those primordia (Plate III, fig. 11 and 12). Serial sections show that the "M-2" traces arise by a lateral branching from the "L-3" traces lower in the axis (Plate III, fig. 7, 8, and 9). In Plate IV, figures 4 and 5 the stippled cells show the origin of an "M-2" trace. The cell drawing in figure 6 is at a lower level where the branches forming the "M-2" trace have not yet separated from the "L-3" traces.

The traces "M-1" (Plate II, fig. 5) contain provascular cells at approximately the stage of development of those entering an emerging primordium. Likewise, the "L-2" traces are at a comparable stage of differentiation and are scarcely distinguishable from the provascular ring. These groups are not easily followed in transverse serial sections, but they can be determined in bias longi-sections that show the provascular cells of the "M-1" traces separating the "L-2" traces and uniting above a gap composed of ground meristem near the base of the apical dome. This is partially demonstrated in Plate V, figure 2 which shows the provascular meristem on the right side of the section near the location of an "L-2" trace. As previously mentioned, other sections of this same bud show the provascular cells of the "M-1" trace to be connected with the "L-2" traces, and to differentiate acropetally into the base of primordium I on that side of the axis.

Further confirmation of the origins and acropetal extension of provascular traces can be found in the traces of older primordia cut in bias longi-sections.

Figures 3 and 4 of Plate V are sections tangential to a lateral trace of one of primordia III, and show the leaf gap just above a lateral trace to one member of primordia V. Referring again to figure 7, Plate II, the "L-3" traces in the diagram can be followed in serial sections to their origins from the "L-4" and "M-4" traces flanking them. Thus each "M-4" trace contributes to each of the "L-3" traces on its side of the axis.

In Plate V, figures 5, 6, and 7, the bias longi-sections show the origin of an "M-2" trace from the "L-3" traces flanking it. Figures 5 and 6 show the corresponding leaf gap, and also the "M-4" trace at its level of divergence from the axis. It should be noted that the origin of both median and lateral traces to any one pair of primordia occurs at a level about two nodes below their primordia.

Protophloem and protoxylem.—Although a complete analysis of the maturation of protophloem and protoxylem was not attempted, the differentiation and maturation of these elements above the fourth internode will be described.

According to Esau (1938) the protophloem of tobacco differentiates acropetally and continuously from older traces into the young primordia. When the first phloem has reached the level of a primordium base, the first protoxylem appears at the same level opposite the protophloem. Further differentiation of the protoxylem continues both basipetally and acropetally. The order of vascular differentiation in *Garrya* appears to be the same.

Just above the level of insertion of primordia IV (Plate III, fig. 5), the "M-3" traces contain no mature protoxylem and protophloem. At the base of the insertion of primordia IV, each "M-3" trace contains one protophloem element in early maturation. No protoxylem in maturation could be found in the "M-3" traces down to their origin.

On the other hand, the "L-4" traces at a level of the insertion of primordia IV each contain one or two maturing protophloem elements opposite one protoxylem element. Approximately the same degree of maturation was found in these traces up to the upper petiole levels of primordia IV, but in the laminar regions only one or two protophloem elements were found.

The "M-4" traces in the petiole regions of primordia IV each contain three or four protophloem elements. The same numbers of protoxylem elements were found opposite the phloem, but the individual cells appeared to be less uniform in maturation than were the protophloem cells. The maturation of both tissues was approximately the same down into the bases of primordia IV (Plate III, fig. 9).

The main differences in the direction of protophloem and protoxylem differentiation are best illustrated in sections showing their relative times of appearance in the "M-3" and "L-4" traces. Examination of transverse sections of a number of buds showed that the protophloem differentiates acropetally from the axis into the primordia. The protoxylem appearing in either an "M-3" or "L-4" trace in

Plate V. Fig. 1-10.—Fig. 1. Bias longisection of foliage leaf bud showing the provascular tissue of a primordium continuous with that of the axis. $\times 120$.—Fig. 2. Arrows indicate the provascular cells described in the text. $\times 266$.—Fig. 3. Bias longisection tangential to the lateral trace of a primordium $500\ \mu$ long. $\times 120$.—Fig. 4. Bias longisection about $15\ \mu$ inward from figure 4. Arrow below points to a lateral trace to a primordium two nodes below the one belonging to the lateral trace shown above the leaf gap. Joined arrows indicate the branches which fuse to form the lateral trace above the gap.—Fig. 5. Bias longisection tangential to a primordium of the second node ($500\ \mu$ long), arrows indicate a portion of

the internode below its respective primordium is interrupted for a short distance just below the insertion of the primordium. But, at the insertion of the primordium, one or two protoxylem elements are present when the protophloem has reached that level.

The acropetal extension of the protophloem in advance of the protoxylem appears to be correlated with the nature of the first provascular cells. As Esau (1938) has pointed out, there is no sharp distinction between the differentiation of xylem from provascular cells and its early formation from cambium, because provascular cells may divide like cambium. The first protoxylem elements in *Garrya* are differentiated from only a few of the innermost cells of a provascular strand adjacent to the rib-meristem. All subsequent xylem formed prior to obvious secondary growth arises in the innermost region of the provascular groups from tangentially dividing cells. It then appears that most of the provascular meristem which is first evident at the bases of leaf primordia differentiates into phloem. It is even likely that the provascular ring in the base of the apical dome, and the first appearing provascular cells in an emerging primordium are actually "primordial phloem" cells.

INTERNAL DIFFERENTIATION AND MARGINAL GROWTH OF CATAPHYLL AND FOLIAGE LEAF PRIMORDIA.—From the illustrations in Plate III, figures 11 and 12, it is evident that cell vacuolation has already begun in primordia II by the time primordia I are emerging. At the levels illustrated, the abaxial sides of the primordia II are composed of cells already enlarged and somewhat vacuolated. Lateral to the median traces additional cell enlargement and vacuolation have begun, and there are a few subsurface cells on the adaxial sides showing some enlargement and vacuolation. By the time that a leaf primordium has begun apical growth (Plate I, fig. 5), the abaxial side begins to show slight cell enlargement and vacuolation in its ground meristem. About the time the next pair of primordia is being initiated, the ones just preceding are approximately $100\ \mu$ long on the abaxial side and show pronounced cell vacuolation in the abaxial, subsurface region, but this differentiation has scarcely begun on the adaxial side (Plate V, fig. 2 shows vacuolation "ab" on the abaxial side of a primordium in bias section). When primordia are well over $100\ \mu$ in length the abaxial side shows an even greater amount of vacuolation than does the adaxial side (Plate I, fig. 1—note the youngest primordia with distinct traces).

Vacuolation is more rapid in cataphyll primordia than in foliage leaf primordia (compare Plate V, fig. 8 and 10). Cataphyll primordia of catkins show

nearly as much internal differentiation as do foliage leaf primordia nearly twice as large (Plate I, fig. 1 and 3).

While cell vacuolation spreads laterally and acropetally in the primordia, zones of greater meristematic activity are retained in the apical, marginal, and to some extent in the subsurface cells of the abaxial and adaxial regions. Rather than delimit the apical and marginal zones as being composed of subsurface cells only, the apical and marginal meristems are here considered as including the protoderm which is distinct from the subsurface cells only by position and the fact that all cell divisions in it are anticlinal. The apical meristem contributes to growth in length and the marginal meristem contributes to lateral extension of the cataphylls and to laminar extension of the foliage leaves. The abaxial and adaxial meristems contribute to growth in thickness of the basal regions of the primordia.

When cataphylls have reached the stage of development characteristic of the third and fourth nodes, the apical and marginal meristems become progressively less active. Before this stage is reached, lateral evagination from the apical dome is producing the lateral wings of the paired cataphylls. At the same time, the general shape of the young cataphyll has been determined and the lateral wings of the paired primordia become joined; further growth becomes less dependent upon mitotic activity, and more dependent upon cell enlargement and maturation.

The formation of the lateral wings of petiolar bases is quite similar to that just described for cataphylls. The bases of foliage leaf primordia at the second node have united (Plate III, fig. 1-5), but the joined wings are not pronounced until later stages in the development of the primordia. The lateral extension of the petiolar base is never as pronounced as are the wings of cataphylls. Cataphylls of catkins show greater apical extension of lateral wings than do the cataphylls of foliage shoots. These differences are correlated with like differences in the activity of the marginal meristems in cataphyll and petiolar bases.

As appears to be common in Angiosperms, the "pleuroplastic" development (Prantl, 1883) of foliage leaf primordia is found in *Garrya*. Enlargement of the petiolar portion begins when the primordium is about $400\ \mu$ in length, or at the third node, and is preceded by pronounced cell vacuolation in the basal regions of the primordium. A leaf at the fifth node possesses a well-defined petiolar region extending more than a third its length. There is a noticeable reduction in marginal meristematic activity in the pe-

the median trace.—Fig. 6. Bias longisection about $10\ \mu$ inward from figure 5.—Fig. 7. Bias longisection about $20\ \mu$ inward from figure 5. Note the median trace to a primordium two nodes below the one shown in figure 5. Above the leaf gap the arrows indicate the branches of (and their fusion to form) the median trace to the primordium shown in figure 5.—Fig. 8. Transverse section of a cataphyllary bud at the basal level of the apical dome. Note: early vacuolation in the younger primordia, lack of activity in the marginal meristems of older primordia, intercellular thickenings in the mesophyll of the older primordia. $\times 120$.—Fig. 9. Transverse section of a cataphyllary bud showing the tip of the apical dome. S—sclerides. $\times 120$.—Fig. 10. Transverse section through a foliage leaf bud above the apical dome. The oldest primordium shown is cut through the base of the lamina and shows the marginal meristem of the lamina as well as the cambium-like activity in the adaxial, petiole-midrib region. Abaxial activity is less pronounced. Compare with figure 8. $\times 120$.

tiolar region as compared with the lamina. Activity of the marginal meristems in the lamina greatly extends the mesophyll. There is little adaxial and abaxial activity in the laminar region except locally in the midrib area, and even here it becomes diminished. The abaxial and adaxial meristems of the young petiole, however, are quite active.

At about the time the differentiation into petiolar and laminar portions becomes evident, cambium-like activity in the abaxial and adaxial regions of the primordia may be distinguished (Plate II, fig. 4-6, "d"). At this stage of development, these divisions are more pronounced on the abaxial side and extend the full length of the petiole-midrib region (see Plate III, fig. 10). In the lower laminar portion of a leaf at the fifth or sixth node this activity is greater on the adaxial side (Plate V, fig. 10). In a primordium of this age the petiolar region is over 300 μ thick and the laminar region is about 100 μ deep and composed of five to seven mesophyll cell layers. Internal differentiation into palisade and spongy parenchyma does not occur until the primordium is 5 mm. or more in length.

The shifting of activity from the abaxial to the adaxial side of the petiole-midrib in *Garrya* is similar to the type of growth described by Schüepp (1929) for *Acer pseudo-platanus*. It is in contrast to the constant adaxial activity in the young petiole as has been described for a number of Angiosperms by Bouygues (1902), Cross (1937, 1938), Foster (1935 a and b), Prantl (1883), Troll (1935), and others.

The "marginal meristem" described by Louis (1935) as occurring in the axis of the shoot is a continuation of the abaxial meristem of the cataphyll and foliage leaf primordia. In *Garrya*, the abaxial meristem is still active in the lower levels of the bases of older primordia (Plate II, fig. 4-7). It is still present in internodal sections considerably lower than the fourth internode, and is traceable to several inches below the apex where it becomes less evident, but appears to give rise to the phellogen.

In contrast to the foliage leaves, the cataphyll primordia of *Garrya* show considerable activity in the abaxial meristem and only an insignificant activity in the adaxial meristem (Plate V, fig. 8 and 9). This method of growth is quite similar to that described by Foster (1935b) for *Carya* cataphylls. The reduced activity on the adaxial side appears related to the early retardation of meristematic activity in cataphylls and the subsequent more rapid differentiation of internal tissues. Large druses and sclerides appear in the abaxial regions of cataphyll primordia of the fourth and fifth nodes (Plate V, fig. 9).

Some histogenetic features of the marginal meristems.—Both cataphyll and foliage leaf primordia, even at early stages of development, possess a protoderm derived from the tunica, and an inner meristem initiated by the corpus of the shoot apex (Plate I, fig. 5 and 6). Careful examination of the surface layer during all stages of development revealed no periclinal divisions even in the axils; thus the protoderm re-

mains discrete from the time it is differentiated in the embryo. Numerous anticlines in the protoderm increase the surface layer of the primordium.

The apical and marginal meristems of both foliage leaf and cataphyll primordia exhibit only very short rows of cells arising from periclinal divisions (Plate III, fig. 11 and 12), and these are soon obscured by irregular divisions (Plate III, fig. 10; Plate V, fig. 9). This is quite in contrast to the sort of activity described by Foster (1937) for the marginal meristem of *Rhododendron* cataphylls, and by Cross (1936) for *Morus*. Pronounced linear rows of cells arise from periclinal divisions in the margins of *Rhododendron* cataphylls, and in *Morus* short filaments of cells arise from a marginal surface cell. As previously mentioned, the apical and marginal meristems in *Garrya* are regarded as including the protoderm. This general interpretation is supported by the behavior of the protoderm in *Rhododendron* cataphylls because cells are added to the inner tissues by periclinal divisions in the protoderm and the resulting derivatives.

In some features the marginal and apical meristems of cataphylls in *Carya*, described by Foster (1935a and b) are more nearly like those in *Garrya*. In *Carya* the tunica is bi-seriate and the outer layer gives rise to a discrete protoderm while the inner layer contributes to the subsurface cells at the margins of the cataphylls. Short, cambium-like rows of cells are formed by periclinal divisions of the marginal meristem. In *Garrya* the outer cells of the corpus, together with the protoderm, provide the origin of the apical and marginal meristems of the primordia; the cambium-like rows of cells in the marginal meristem, however, are less evident than in *Carya*.

Transition cataphylls.—The transition forms in *Garrya* are similar to those of *Carya* (Foster, 1935b) in periodicity of formation (Plate II, fig. 3). During expansion of the foliage bud, the axillary buds, maturing acropetally, develop several pairs of cataphylls in addition to their prophylls. Transition forms may appear on these axillary shoots just before foliage leaf production begins the next season of active growth. Also, transition forms on the terminal buds may arise as the active season of growth merges into the season of cataphyll production. When a catkin cluster differentiates from a terminal bud, transition forms may be found between the catkin cataphylls and the foliage leaves of the previous year.

Generally those transition cataphylls formed just prior to the season of active growth develop a characteristic aborted lamina that may become as much as two centimeters in length and three millimeters in width. The other transition cataphylls show less development, but they are more elongate and reflexed than normal cataphylls. While no attempt was made to study these transitions in detail, examination of transverse sections of buds collected at the appropriate time of year revealed considerable variation in the amount of activity in the apical and marginal meristems of primordia of comparable ages. Some

cataphyll primordia retain such activity much longer than do others. At the same time, internal differentiation appears to be more pronounced in normal cataphylls than in those produced during the transition period.

The fact that the cell series resulting from marginal meristem activity in *Garrya* cataphylls are less pronounced than those described by Foster (1935a and b) for *Carya* may indicate some relationship to differences in size of the organs in these genera. In normal cataphylls of *Garrya* the activity of the apical and marginal meristems is noticeably less by the time protoxylem can be distinguished in the traces of the primordia, and mitoses are few when the cataphyll is but one millimeter long.

In view of the above observations, the cataphylls of *Garrya* are regarded as equivalent to the bases and lateral sheaths of the petiolar regions of the foliage leaf. This is evidenced not only by histogenetic features, but also by the variability of the aborted laminar portion of the transition cataphyll.

Discussion.—As previously discussed in the paragraphs on the shoot apex, the variable appearance of the tunica-corpus in *Garrya* is correlated with plastochron periodicity, but only one discrete tunica layer is found throughout the annual history of the apex. The fact that variability in the numbers of tunica layers exists in the apices of other Angiosperms serves to emphasize the dynamic aspects of shoot growth. Satina, Blakeslee, and Avery (1940, 1941) working with colchicine-induced periclinal chimeras in *Datura* apices have opened a promising field in which the problems of tissue and organ initiation may be studied more completely.

The tunica of axillary buds forms directly from the protoderm of the axil in *Garrya*. Zimmerman (1928) has shown in *Hypericum* that there are differences in the behavior of tunica layers of axillary buds and terminal buds. In early ontogeny the axillary bud of *H. uralum* possesses three tunica layers; the innermost of these layers, by periclinal divisions, contributes to the corpus and later to the establishment of the third and fourth tunica layers of the shoot apex. On the other hand, the apex of the terminal bud possesses four "permanent" tunica layers. Krumbholz (1925) reported a discrete subepidermal layer in both apex and leaf primordium of *Oenothera*. The subepidermal layer, together with the protoderm, contributes to the apical and marginal meristems of the lateral organs during their early development, but does not lose its identity in the initiation of axillary buds.

Variations in numbers of tunica layers of terminal and axillary buds also have been reported by Schmidt (1924) and other workers. Boke (1940) reported rare periclinal divisions in the "T-2" layer of *Acacia* terminal apices, and regarded variations from a four-layered to a five-layered condition of the apical meristem as "a temporary, divergent development of the outer corpus." That such variations may imply relationships to plastochron periodicity has already been mentioned with reference to *Garrya* apices.

In apices for which a number of tunica layers has been reported, the contributions of tunica and corpus to the lateral primordia remain distinct only until random planes of division in the primordia obliterate these layers. The general mode of initiation of primordia from subsurface layers by periclinal divisions in most Angiosperms differs little from the mode of leaf and cataphyll initiation in *Garrya*. There are, of course, differences in the formation and activity of the apical and marginal meristems of the primordia, but these may be related to size and shape of the mature organs, or to special peculiarities. Monocotyledons also appear to be fundamentally different from Dicotyledons in their apical activity. This difference is evident in such examples as the superficial origin of leaf primordia in *Triticum*, as described by Rösler (1928), and *Avena*, as described by Kliem (1937). In the Palmaceae, however, Ball (1941b) reports that the apices of *Phoenix* are ginkgooid in organization, while *Washingtonia* and *Trachycarpus* possess apices similar to those of the Dicotyledons.

The acropetal differentiation of provascular tissue from the shoot into the primordia of leaves and cataphylls supports the concept of the leaf as a lateral branch system. Arber (1930, 1941) has modified a previous interpretation of plant organs and now considers the leaf and root as partial shoots. As yet, however, an inadequate number of Angiosperms and other vascular plants have been studied to warrant any general conclusions concerning the implications of acropetal provascular differentiation.

SUMMARY

The vegetative apex of *Garrya* possesses a one-layered tunica, discrete throughout its annual history and continuous with the protoderm. Periclinal divisions in the flanks of the corpus initiate decussate primordia. Variations in the stratification of the corpus are related to plastochron periodicity.

The growth of the shoot is much slower during cataphyll formation than during foliage leaf formation. Occasional transition cataphylls occur at the end of each of these two growing seasons. Both cataphyll and foliage leaf primordia undergo apical and marginal growth. Meristematic activity diminishes first in the abaxial and basi-lateral regions and lastly in the adaxial and apical regions of the primordia as progressive cell enlargement and vacuolation take place. Early retardation of the apical and marginal meristematic activity, accompanied by comparatively rapid internal differentiation, distinguishes the cataphyll primordia from the foliage leaf primordia.

The abaxial meristem of the primordia is continuous into the internodes of the shoot. In older internodes, as the bud expands, this meristem appears to form the earliest phellogen.

The petiolar region of the leaf is distinct when the primordium is 500 μ in length and the adaxial meristem has become more pronounced in activity than the abaxial meristem.

The vascular meristem of the cataphyll and foliage leaf primordia is initiated as a ring of provascular cells bordering the rib-meristem of the apical dome. Early differentiation of traces from this ring is associated directly with the initiation of primordia. The median and lateral traces of the primordia diverge from older traces in the axis. These diverging traces differentiate acropetally and join above

the leaf gaps. Their most distal extension in the axis is in the apical dome, quite close to the earliest initiation of primordia, and further differentiation proceeds acropetally into the emerging primordia.

COMPARATIVE CYTOLOGY OF STERILE INTRA- AND FERTILE INTER-VARIETAL TETRAPLOIDS OF ANTIRRHINUM MAJUS L.¹

A. H. Sparrow, M. L. Ruttle, and B. R. Nebel

AUTOTETRAPLOIDS, WHETHER of spontaneous origin or induced artificially, are often characterized by reduced fertility. In some cases the most sterile tetraploids are those produced from highly homozygous diploids. Thus in tomato the most sterile tetraploids were obtained from a haploid through the diploid (Lindstrom and Humphrey, 1933) and in maize from inbred lines (Randolph, 1941). A similar condition was reported in *Antirrhinum majus* L. (Emsweller and Ruttle, 1941). Intravarietal tetraploids were relatively sterile and intervarietal tetraploids relatively fertile.

Meiotic irregularity associated with multivalent chromosome association has been cited by Darlington (1937) and Kostoff (1939) as one of the factors responsible for the reduced fertility of autotetraploids. On the other hand Lindstrom and Humphrey (1933) and Randolph (1941) report no correlation between the degree of sterility and the number of meiotic chromosome associations of first metaphase. In view of the above difference in observation the present study was initiated in order to determine, if possible, the relationship of meiotic chromosome behavior to sterility in autotetraploid snapdragons.

CYTOLOGICAL METHODS.—Material was fixed in 2:1 alcohol-acetic acid and placed in cold storage at about 34°F. Two or three changes of the fixative within the first twelve to twenty-four hours seemed to give better results, especially when a large amount of material per vial was involved. Smears were made in iron acetocarmine not less than twenty-four hours after fixation, then heated over a steam bath, pressed and sealed. Longer fixation was preferable, and good results were obtained even after storage for two to four months at 34°F. Sealed smears also kept well in cold storage if placed in a tightly covered container with a layer of 45 per cent acetic acid in the bottom to reduce evaporation. Slides were made permanent by running them up through alcohol-acetic

^a Twenty cells of 41-56-8, and fifteen from 41-503-1 were analyzed for metaphase associations, only ten from other plants.

^b This value is the mean of three sister plants. No pollen was obtained from 41-36-28.

3:1, 9:1, two changes of absolute alcohol and mounting in euparal.

OBSERVATIONS.—The cytological factors which may contribute to the differential fertility in the two types of tetraploids include degree of metaphase pairing, anaphase laggards and unequal segregation at first and second anaphase leading to aneuploid nuclei (fig. 1 to 7). The data in regard to these factors have been tabulated, and differences between the intra- and intervarietal tetraploids tested for significance by the χ^2 or by the standard error method. In some cases coefficients of variability were also calculated and tested for significance.

Chromosome associations at late diakinesis and first metaphase in ten or more cells from each of seven intra- and six intervarietal tetraploids ($4n = 32$) and one intervarietal triploid ($3n = 24$) were analyzed (table 1 and fig. 1 and 2). Table 1 shows that, whereas there is a significant difference in the amount of aborted pollen in the different plants, there is no such obvious difference in the chromosome behavior. Since in most cases only ten cells from each plant were analyzed, the combined data from all the intravarietal tetraploids have been

mosomes in one group, sixteen in the other and, at the right, one dividing univalent. Intravarietal tetraploid (40-224-1).—Fig. 5. First anaphase with fifteen chromosomes in one group and seventeen in the other. In anaphase groups of both figures 4 and 5 there are non-disjoined chromosomes. Intervarietal tetraploid (40-285-1).—Fig. 6. Irregular second anaphase with lagging chromosomes and dividing univalents. Intravarietal tetraploid (41-69-8).—Fig. 7. Second anaphase showing two groups with fifteen chromosomes each, one group with eighteen and one group with sixteen chromosomes. Intravarietal tetraploid (41-56-8).

compared with the grouped data from the intervarietal tetraploids (tables 2 to 4). The frequency distribution of quadrivalents, trivalents, bivalents and univalents in both types is given in table 2, as well as the mean numbers of each with their standard errors.

The mean number of quadrivalents in the intravarietal was 4.99 ± 0.165 and for the intervarietals it was 5.05 ± 0.148 , ranging from 2 to 7² per nucleus. Bivalents ranged in number from none to twelve with means of 5.18 ± 0.296 and 5.15 ± 0.304 in the intra- and intervarietals respectively. Differences in the means in both cases are obviously not significant. The great majority of chromosomes are involved in quadrivalent or bivalent formation (approximately 63 and 32 per cent respectively) while univalents and trivalents together make up only about five per cent of the total (table 3).

Differences in total numbers of quadrivalents, trivalents, bivalents and univalents between intra- and intervarietal tetraploids were also tested by the χ^2 method and found not to be significant (table 3). Nor was there any significant difference between the two types of tetraploids in the percentage of cells which had eight to ten, eleven, twelve or thirteen to sixteen metaphase associations (table 4). (Cells with all chromosomes paired as bivalents would have the maximum of sixteen associations, while cells with all chromosomes in quadrivalents would have only eight.) Variability in number of quadrivalents and bivalents was also tested, but again the differences were not significant.

² Later an occasional cell with eight quadrivalents was observed but none was included in the cells analyzed for metaphase pairing.

TABLE 2. Frequency distribution and means per cell of the main types of meiotic associations in intra- and intervarietal tetraploids.

Univalents															
Intravarietal	80	42	16	16	3	2	1	0.88 ± 0.127
Intervarietal	60	37	7	13	2	1	0.72 ± 0.132

The number of lagging chromosomes at first anaphase (fig. 3) was scored from at least fifty cells from each plant studied. The percentages of cells with zero, one, two, and three or more laggards per cell are given in table 5. The χ^2 test shows that the number of laggards in the intravarietal anaphases is significantly greater than in the intervarietal ones

somes were frequently noted at late anaphase, especially in cells with unequal segregation. These are, presumably, bivalents or parts of multivalents which failed to disjoin at early anaphase (fig. 4 and 5). Lagging univalents divided at first division (fig. 4) but frequently not in time to be incorporated into the telophase nuclei. Their loss would increase the num-

$$\Sigma\chi^2 = 1.328; \quad df = 3; \quad P \text{ is between .8 and .7}$$

(P is less than 0.01). This is especially true of cells with two or more laggards.

The laggards observed at first anaphase were not all univalents. Bivalents or larger associations were sometimes delayed on the plate and either failed to disjoin or disjoined belatedly. This may partially account for the fact that there is a significant difference in anaphase laggards but not in univalents at metaphase. Associations of two or three chromo-

ber of aneuploid pollen grains and would probably contribute to the higher mean percentage of aborted pollen observed in the intravarietal tetraploids (table 1).

Chromosome counts were made in 268 first anaphases in which all of the chromosomes had moved off the plate and were clearly segregated into two groups. The percentages of cells with equal (16:16) and unequal (17:15 or 18:14) segregations are given in table 6. The mean percentages with uneven segre-

-69-8	72.0	28.0	0	25
Mean	73.9 ± 1.81	20.3	5.8	129
		26.1 ± 1.81		
Intervarietal				
40-257-1	86.7	13.3	0	30
-281-1	80.8	19.2	0	26
-285-1	71.0	29.0	0	31
41-12-71	72.0	28.0	0	25
-52-9	77.8	22.8	0	27
Mean	77.6 ± 2.12	22.4 ± 2.12		139

gations were 26.1 ± 1.81 for intravarietals and 22.4 ± 2.12 for intervarietales. The difference in total number of unequal disjunctions is not significant, but the intravarietals had 5.8 per cent of 18:14 segregations as against none in the intervarietales.

At second anaphase lagging chromosomes frequently occur (fig. 6). Twenty-seven second anaphases without laggards were selected from one intravarietal tetraploid (41-56-8) which had 71 per cent normal segregation at first anaphase. Of these twenty-seven second anaphases seventeen (63 per cent) had the expected number of chromosomes (16:16:16:16), while seven had 17:17:15:15, two had 16:16:17:15, and one (fig. 7) had 16:18:15:15. Of the total of 108 nuclei 35 had either more or fewer than 16 chromosomes, and yet aceto-carmine smears showed that this plant had only six per cent of aborted pollen (unusually low for an intravarietal). In an intervarietales tetraploid (41-52-9) with 70 per cent normal first anaphase segregation, 75 per cent of the 20 second anaphases counted had the expected segregation and 25 per cent had 17:17:15:15. This plant was highly fertile, while the intravarietal one mentioned above, with 32 per cent aneuploid second anaphase nuclei and a lower percentage of aborted pollen, was highly sterile. The extreme differences in seed set are obviously not caused merely by differences in chromosome behavior during microsporogenesis.

The mean percentages of unaborted pollen in the plants examined cytologically and known to have thirty-two chromosomes was 55 ± 9.3 for intravarietals and 86 ± 3.0 for intervarietales (table 1). The corresponding coefficients of variability are 44.6 ± 1.41 and 8.65 ± 2.52 . The difference is significant and indicates that there is a greater variability in the amount of pollen abortion in the intravarietal than in the intervarietales tetraploids. The intravarietals

have a significantly higher percentage of aborted pollen than the intervarietales. The former, however, average more than 50 per cent unaborted pollen, of which a reasonable proportion (up to 70 per cent) will germinate in sugar solution, and yet they set relatively few seeds when selfed. The difference in seed set in the two types of tetraploids is much greater than can be accounted for on the basis of differences in male sterility, i.e., pollen abortion.

Chromatin bridges (fig. 3) were observed in all the tetraploids which were examined in detail. They were usually not accompanied by fragments, although the latter were sometimes present. Second division bridges were also observed in eight of the thirteen plants, despite the fact that comparatively little attention was paid to second division figures. In addition to the bridges which resemble dicentric, some of those seen at first anaphase were obviously the bivalents or quadrivalents, mentioned above, which had stayed on the metaphase plate longer than the rest and were then apparently unable to disjoin normally, and hence remained for a time connected by attenuated strands of chromatin.

Similar bridges are also present in diploid control material grown in the greenhouse. In a clonal line of the variety Alaska the mean frequency of cells with bridges was 0.65 per cent for diploid branches and 1.18 per cent for tetraploid branches. The number of cells examined was 2921 and 1110 respectively.

The cause of the bridges and attenuations is not known, but it may be relevant that Ernst (1938) found numerous translocations, inversions and deficiencies following temperature shock treatment of diploid snapdragons.

It may be added that spindle irregularities not included in the above discussion were observed in three different plants. In one tetraploid and one diploid derived from a colchicine-treated plant, many second divisions had only one spindle instead of two, the chromosomes being arranged in one large metaphase plate, forming two large telophase nuclei in place of the usual quartet. These appeared in the pollen as giant grains or at earlier stages as dyads. In another intravarietal tetraploid many second divisions had more than the normal number of spindles, ranging as high as six. This seemed to be the result of a faulty first division which failed to congregate the chromosomes at telophase. The condition resembles very closely the divergent spindles reported by Clark (1940) in maize, although in her case they arose in the F_2 of a plant fertilized with pollen which had received ultraviolet radiation.

DISCUSSION.—Unequal segregation from quadrivalents has been cited as a cause of sterility in tetraploids by Darlington (1937), Kostoff (1939) and others. Raptopoulos (1941) has reported an inverse relationship between fertility and the mean number of quadrivalents in autotetraploid cherries. Contrary to these observations, the results of Lindstrom on tomato, Randolph on maize and the present studies on snapdragon do not indicate any correlation be-

tween sterility and the number of quadrivalents. Nor can the reduced fertility be attributed to a lack of pollen. Other factors must be operative. Incompatibility and female or zygotic sterility are suggested.

If unequal segregation at first anaphase is due to irregular disjunction from quadrivalents the frequency of non-disjunction can be estimated. The mean number of quadrivalents is five per pollen-mother cell, and roughly one anaphase in four shows unequal segregation. Thus one in twenty of the quadrivalents fails to disjoin normally. The resultant aneuploidy might be considered an important factor in causing sterility in the intravarietal tetraploids were it not for the fact that the intervarietals also have many aneuploid nuclei but are highly fertile.

Unequal segregation from quadrivalents can not be accepted as an explanation for the degree of sterility observed. However, aneuploids occur rather frequently in tetraploid populations of both maize (Randolph, 1941) and snapdragon (Straub, 1941), such plants often being indistinguishable in phenotype from plants with the regular number. Randolph reports that approximately one half the plants in a tetraploid progeny do not have the balanced chromosome number. This is of interest in that our observations show that approximately one in four of the second anaphase nuclei are aneuploid. Assuming that a comparable amount of unequal segregation occurs in macrosporogenesis, then random union of male and female gametes should give nine euploid to seven aneuploid zygotes. The additional aneuploidy resulting from the loss of laggards would bring the ratio up at least to the 1:1 ratio reported for maize.

The data presented above show that the intervarietal tetraploids which give a high seed set also have a higher average percentage of unaborted pollen than the intravarietals. However, even those intravarietal tetraploids, with only a small percentage of aborted pollen, fall far below the level of the intervarietals in fertility. The reduced fertility of the intravarietal tetraploids, therefore, can not be attributed to a deficiency of pollen, although it may be indirectly related.

The differences in the number of 18:14 segregations and in the number of cells with laggards at first anaphase would contribute to the higher percentage of aborted pollen in the intravarietals. But since the degree of pollen abortion apparently is not correlated with seed set, the differences in fertility in the two types of tetraploids can not be explained on the basis of meiotic chromosome behavior at microsporogenesis. It may be assumed, therefore, that differences in their genetic constitution are responsible. An obvious difference is that the intravarietals are *relatively* more homozygous. It seems probable that in tetraploid snapdragons, as in tetraploid maize (Randolph, 1942), homozygosity *per se* may be re-

sponsible for the reduced vigor and fertility of the more homozygous (intravarietal) tetraploids. Conversely heterozygosity would increase the vigor and fertility of the hybrid or intervarietal tetraploids (cf. Huskins and Smith, 1934 p. 393).

SUMMARY

A comparison of microsporogenesis and the percentage of unaborted pollen in intra- and intervarietal snapdragon tetraploids shows that sterility in the intravarietal tetraploids is not correlated with the mean number of chromosome associations, nor with a difference in the mean valency per cell, nor with the valency percentage, nor with group associations; that sterility as measured by seed set is a concomitant of, but is probably not conditioned by, a significantly higher percentage and greater variability in amount of aborted pollen, a significant difference in the number of laggards at first anaphase and a difference in the number of 18:14 segregations at first anaphase.

These minor cytological differences are not sufficient to account for the large difference in fertility of the two types of tetraploids but may stem from the same origin. A relatively higher homozygosity of the intravarietal tetraploids is considered the probable cause of their greater sterility.

GROWTH HORMONES AS RELATED TO THE SETTING AND DEVELOPMENT OF FRUIT IN *NICOTIANA TABACUM*¹

Robert M. Muir

STUDIES of growth hormones in plants have revealed many interesting aspects of the problem of fruit development. That growth hormones have a causal relationship to fruit development was first demonstrated when Gustafson (1936) induced parthenocarpic fruit development in tomato, *Petunia*, *Salpiglossus* and pepper. Mature fruits without seeds were produced through the use of the growth promoting chemicals indoleacetic, indolepropionic, indolebutyric and phenylacetic acids applied to the cut style. Gustafson (1937) found that extracts of pollen can induce fruit development in many plants and that this effect is not specific. The results of investigations by Laibach (1932) established the close relationship of the effective substances in pollen extracts to the growth hormones. Extracts of pollen and also of animal tissues caused the gynostemium to swell in certain tropical orchids and promoted the growth in length of the oat coleoptile. These facts were the basis for an hypothesis advanced by Gustafson (1939) that growth hormones from the pollen grains and pollen tubes initiate the early stages of fruit development, and after fertilization the developing embryo provides additional growth hormones. This paper deals with direct measurements of the growth hormones in the style, ovary and pedicel of pollinated flowers.

EXPERIMENTAL METHODS.—The plant used in the experiments has been *Nicotiana tabacum* L., Lizard's Tail variety. It was found that flowers and fruit setting could be obtained continually by cutting back the flowering shoots on plants brought in from the field in October and kept in the greenhouse. The concentration of growth hormones was determined by placing the plant tissue on a block of agar and allowing the diffusion of the growth hormones into the agar to continue for several hours (Went, 1928), and the subsequent application of this block unilaterally to a deseeded *Avena* coleoptile using Skoog's (1937) modification of the standard *Avena* test method (Went and Thimann, 1937).

Pollinations were made at different times previous to the diffusion of the hormones. At the time that some flowers were pollinated, others had the tip of the style covered with small lead foil caps to prevent pollination, and these were used as controls. Only flowers which had the stigma receptive and the anthers in the process of dehiscing were used. The flowers were removed from the plants just before the experiment, and each group of pollinations was

treated as a unit in the diffusion of the hormones. Each pistil was divided into three parts: the ovary, and two equal lengths (1.8 cm.) of the style. The three portions of a single pistil were kept together throughout the experiment so that results for each individual pistil were obtained. Immediately upon excision, the basal cut surfaces of the portions were placed for five to ten minutes on moist filter paper to prevent their drying out until set upon the agar blocks which were 2.7 mm. \times 2.9 mm. \times 1.6 mm. Small supports of copper wire were used to hold the segments of the style in a vertical position, and care was exercised to ensure the existence of a film of water between the cut tissue surface and the surface of the agar. One and one-half per cent agar was used in experiments 1 and 2. The weight of the ovaries forty-five to sixty hours after pollination was great enough to crush the agar blocks to some extent, therefore, 3 per cent agar was used in experiment 3. All diffusions were for a period of three hours in an *Avena* test darkroom at a temperature of 25°C. and in the saturated atmosphere of a large petri dish. At the end of the diffusion period the plant tissues were removed and the agar blocks were applied unilaterally to the deseeded *Avena* coleoptiles. The curvatures of the coleoptiles, after five hours, are recorded in table 1.

Both the styles that were used for the determination of growth hormones and others pollinated at the time of the experiment were dissected under a binocular dissection microscope; the cortex was removed from the style and stigma. The strands of conducting tissue and the pollen tubes were stained with aqueous solutions of magenta red and light green S.F. Yellowish, according to the procedure of Buchholz (1931) and the growth of the pollen tubes was observed.

RESULTS AND DISCUSSION.—*Growth hormones as related to pollination and fertilization.*—Table 1 shows that in only a few instances were appreciable quantities of diffusible growth hormones found in the styles or ovaries of unpollinated flowers. The small amounts and their infrequent occurrence are in striking contrast with the results for pollinated flowers. In the styles from flowers pollinated fourteen hours previous to the diffusion of the growth hormones in the first experiment, the pollen tubes had grown through the apical half of the style and a few millimeters into the basal half. Considerable quantities of growth hormones were obtained from both the apical and basal portions of the styles with those from the basal portions being somewhat larger. The quantities obtained from the ovaries were in most cases less than those from the styles at this time. In the second experiment the growth of the pollen tubes was slower than in the first, the tubes having passed through only the apical half of the style twenty hours after pollination. Smaller amounts of

growth hormones were obtained from the portions of styles pollinated eleven hours before the diffusion as would be expected. In all experiments the pollen tubes had grown completely through the style and entered the ovary after forty hours when fertilization may be assumed to occur. At this time the apical portions of the styles contained little, if any, growth hormones; the basal portions still had some diffusible hormone while the hormone content of the ovaries had in all except a few instances increased greatly. Poor contacts between the ovaries and agar blocks are probably responsible for the exceptions. It should be noted, however, that two other causes of variation exist in the technique which are of relatively minor importance. The coleoptiles of *Avena* are not all equally sensitive to the growth hormones and

the pollen tube growth of different pollinations is somewhat variable.

That pollination is responsible for the presence of the growth hormones in the style and ovary of the pollinated flower is shown in two ways: first, the hormones are almost entirely absent from the style and ovary of the unpollinated flower; and second, the distribution of the growth hormones is closely related to the extent of the penetration of the pollen tubes into the style. This may be regarded as supporting the hypothesis advanced by Gustafson (1939) which states: "In normal fruits in which pollination and fertilization are necessary . . . the initiation of growth of the ovary into a fruit results from the auxin brought into it by the pollen tubes." However, the critical test of the hypothesis would be

the demonstration of hormone content in pollen grains and pollen tubes comparable to that obtained by diffusion of the pollinated styles. A number of experiments having this as their object were performed with *Nicotiana*, *Datura*, *Antirrhinum* and *Lilium*. Although excellent growth of pollen tubes *in vitro* was obtained, satisfactorily consistent results were not. In no instance was an amount of growth hormones obtained, by the extraction of pollen grains and pollen tubes of *Nicotiana*, which was equivalent to that obtained from the style of a pollinated flower by diffusion.

In evaluating these experiments it must be borne in mind that there is ample evidence to show that the diffusion method and the extraction method do not always give comparable results. It is possible that none of the methods employed here, and which are in general use for the extraction of plant growth hormones, is adequate for comparisons of such a nature.

Van Overbeek, Conklin, and Blakeslee (1941) have recently advanced the hypothesis that, since only a small amount of the total potential growth hormones is present in active form in the coleoptile tip of the seedlings of corn, a similar condition might occur in the young ovary; and "... the diffusible substance from germinating pollen which ultimately causes enlargement of ovaries and ovules may be some prosthetic group, which, when properly combined in the ovary, forms an enzyme which activates the auxin precursor." Skoog and Thimann (1940) have reported what appeared to be the liberation of auxin from proteins of *Lemna* tissue by the addition of proteolytic enzymes. Wildman and Gordon (1942) have shown that auxin is associated with proteins isolated from the leaves of spinach and that the auxin can be released by enzymatic hydrolysis. It is thus possible that the growth hormones found in the style and ovary are not transferred from the pollen but are produced *in situ* as the result of an enzymatic hydrolysis of proteins. To restrict the contribution of the pollen tube to a prosthetic group which combines in the ovary to form an enzyme is unnecessary, for the data presented here show that the pollen tubes do not need to reach the ovary before a considerable amount of growth hormones can be obtained from the style.

Strasburger (1886) found that pollen grains of several plants could hydrolyze a starch paste to sugar, indicating diastatic activity. It was also observed that equal activity was displayed by the intact grains, by grains which discharged their contents, and by germinated pollen. Strasburger's observations were limited to the activity of pollen tubes in the case of *Nicotiana* for the pollen germinated readily in the starch paste medium. Paton (1921) found that in most cases the pollen tubes make their way between the cells of the style by digesting the pectin of the inner lamella with a pectinase. Testing the pollen of eighteen species, she found that all contained amylase, invertase, catalase, reductase and pectinase; pepsin, trypsin, erepsin, and lipase were demonstrated in some and not in others. The inver-

tase and amylase activity of ground pollen was greater than that of unground pollen, while germinated pollen was no more active than ungerminated pollen. The amylase activity of unground germinated pollen was almost as great as that of ground germinated pollen, however. It does not seem improbable, therefore, that along with the other secretions of the pollen tubes during their penetration of the style, there is an enzyme which can release the growth hormones from whatever entities, such as proteins, they may be bound to in the inactive form.

Growth hormones as related to flower abscission.—If pollination and fertilization do not occur, the flowers of *Nicotiana* wither and abscission at the base of the pedicel occurs within three to four days after the flower reaches full development. With such high concentrations of diffusible growth hormones in the fertilized ovary, it seemed probable that appreciable quantities of growth hormones would be continuously moving downward through the pedicel of the fertilized flower. Several experiments were performed to establish this as a fact. The method was essentially the same as that described above, except that only the ovary (without the style) and the pedicel were placed on the agar blocks for diffusion of the growth hormones. The receptacular enlargement of the pedicel was removed and a fresh cut was made at the base of the pedicel before the diffusion.

The curvatures obtained from these diffusions are recorded in table 2. The diffusion in experiments 1 and 2 was into 1.5 per cent agar blocks, while that of experiment 3 was into 3 per cent agar. All were for a period of three hours. The curvatures indicate, as in the preceding experiments, that there is a marked increase in the diffusible growth hormones at the time when the pollen tubes reach the ovary (approximately thirty-five to forty hours after pollination) and at this time, or somewhat later, appreciable, and in some cases considerable, amounts of growth hormones move through the pedicel. Enlargement of the capsule begins about fifty-five hours after pollination under these conditions and larger amounts of growth hormones are present with large quantities moving through the pedicel. The unpollinated controls had no detectable quantities of growth hormones in the pedicels and only small amounts, if any, in the ovaries.

It is concluded from these experiments that the growth hormones from the ovary move through the pedicel and prevent the abscission of the flower by inhibiting the development of the absciss layer, thus allowing the ovary to develop into a fruit. Several investigators working on the abscission of leaves have shown that the growth hormones exert a definite inhibitory effect on the development of the absciss layer. Laibach (1933) found that orchid pollinia inserted in the split ends of petioles of debladed leaves of *Coleus* and several other plants delayed abscission of the petioles twelve to twenty days longer than in the controls. A lanolin paste containing the growth hormones from pollinia of tropical orchids also retarded abscission for eight days. LaRue (1936) ob-

served that synthetic heteroauxin (indoleacetic acid) applied in agar or lanolin to the cut ends of petioles of *Coleus* and *Ricinus* inhibited the development of the absciss layer for significant periods of time. Similar results were obtained by Myers (1940) who also showed that growth hormones from the leaf blades influence the development of the absciss layer.

The assay of growth hormones by their diffusion into agar emphasizes the mobility they possess. It has been demonstrated that there is a continuous movement of the hormones down the pedicel, while at the same time an approximately uniform concentration of diffusible growth hormones is maintained in the ovary for at least fifty hours after fertilization. That this production and movement of hor-

mones out of the ovary over an extended period of time is important for continued growth of the fruit is indicated by the results of investigations of Gardner and Marth (1937). They found that spraying flowers of *Ilex opaca* with indoleacetic, indolebutyric, indolepropionic, and naphthaleneacetic acids caused fruit set without pollination. However, when a second flush of growth occurred in both pollinated and sprayed plants, the sprayed plants dropped all of their fruit, while none of the pollinated plants dropped their fruit. Gardner and Marth regarded the lack of abscission in the case of the pollinated fruits as probably associated with the development of the embryos within their seeds. That conclusion is substantiated here in so far as fertilization is re-

sponsible for a continuous movement of growth hormones, released in the fruit, through the pedicel.

Another important aspect of the movement of the growth hormones out of the ovary is the part the hormones would have in the development of the conducting elements in the pedicel and other portions of the inflorescence, providing for the movement of food materials into the growing ovary. This development in *Ilex opaca*, according to Gardner and Kraus (1937), is mainly a matter of maturation with only a few additional elements being differentiated from the cambium.

SUMMARY

Direct measurements of diffusible growth hormones were made on styles and ovaries of pollinated and unpollinated flowers of *Nicotiana tabacum*. None or very small amounts were obtained from the portions of an unpollinated pistil, but considerable quantities were found in the portions of a pollinated pistil. The growth hormone concentration was close-

ly related to the extent of the penetration of the pollen tubes into the style—fertilization resulting in the release of large amounts in the ovary.

The data are considered in relation to the hypotheses advanced to explain the initiation of fruit development by pollination. The extraction of pollen grains and pollen tubes did not indicate them to be the source of the growth hormones. It is suggested that the pollen tubes may secrete an enzyme which can liberate the growth hormones from inactive combinations in the style and ovary.

The growth hormones released in the fertilized ovary move downward through the pedicel and prevent abscission of the pistil by inhibiting the development of the absciss layer. These hormones are also probably concerned in the development of the conducting elements through which food materials move into the growing ovary.

INFLUENCE OF OXYGEN TENSION ON RESPIRATION, FERMENTATION, AND GROWTH IN WHEAT AND RICE ¹

David L. Taylor

THE CEREAL grains constitute the most important group of food plants for man. Wheat (*Triticum* spp.) is the leading cereal food of North America and Europe, and rice (*Oryza sativa*) is the chief food of the Orient, where it sustains half the population of the earth. Even in the United States rice has become a crop of considerable importance. Rice is normally cultivated in shallow ponds, filled with water to a depth of six to eight inches during the greater part of the growing season (Jones, 1937). Wheat, however, is always grown under ordinary dry-land conditions, and it is unable to survive more than a brief period of flooding. Submersion in water markedly decreases aeration, and it seems likely that this factor is responsible for the difference in the reactions of wheat and rice to aquatic conditions.

Some fundamental difference between the respiratory systems of these closely related grasses might well be expected to account for their responses to decreased oxygen in the environment. Rice must either be more efficient than wheat in using low concentrations of oxygen, or it must possess a growth mechanism that is only partially dependent upon the limited supply of oxygen. It has long been known that wheat, rice, and other cereal grains can carry on some anaerobic activity.

In an attempt to ascertain the physiological basis for this difference between wheat and rice, a study was made of the influence of oxygen tension, from 0 to 20.8 per cent, on respiration, fermentation, and growth in seedlings of each of these cereal grains.

MATERIALS AND METHODS.—*Respiration studies.*—The studies reported in this paper were carried out during a period of one year, beginning in May, 1941, with seeds of the 1940 crop of Leap's Prolific winter wheat (obtained from A. H. Hoffman, Inc., Landisville, Pa.) and Early Prolific lowland rice (supplied by the Texas Agricultural Experiment Station, Beaumont, Texas). Both are among the leading commercial varieties of these cereal grains. Tests near the close of the work showed that storage of the seeds had produced no significant alteration of the respiratory activity of seedlings grown from them.

Seeds used in the experiments were selected for uniformity in appearance and size. After being soaked for five minutes in a freshly filtered 0.55 molar calcium hypochlorite solution and then rinsed with distilled water, the seeds were placed in large glass culture dishes, on three thicknesses of sterile filter paper moistened with a slight excess of distilled water. These germinators were kept at a temperature of 30°C. in a dark incubator. Approximately three times as many seeds as were required for an experiment were selected and germinated.

Good germination and three-day development of both wheat and rice occurred on filter paper moistened with distilled water. Preliminary tests indicated no important advantage of adding salts or sugar to the germination substrate. Media with ionic balance gave indications of superiority, and the pH value of the substrate had a more marked influence. Wheat germination and development were most rapid on slightly acid substrates (pH 5.0–6.0), while rice development was best in nearly neutral substrates (pH 6.0–7.0).

A period of 25 hours was allowed for wheat germination and a period of 33 hours for rice germination, in order to obtain seedlings of each with roots 5 to 7 mm. long. Secondary roots were evident on the wheat seedlings, but not on those of rice; coleoptiles were developed to a length of 4 or 5 mm.

Groups of wheat and rice seedlings, 25 of wheat or 30 of rice, of the character described were selected and pretreated by soaking them in a sucrose buffer for one hour before they were transferred to each of the respiration vessels charged with the same buffer. The buffer had a pH value of 5.8 and a K/Ca balance of 7.3/1. The buffer solution had the following composition: 0.009 M KH_2PO_4 ; 0.001 M K_2HPO_4 ; 0.0015 M $\text{Ca}(\text{H}_2\text{PO}_4)_2$; 0.117 M sucrose. It was employed in all manometric tests in order to provide a stable medium conducive to maximum seedling activity.

The composition of the buffer was based upon recommendations in the literature supplemented by the tests on seed germination previously mentioned. Numerous studies (Jones and Shive, 1922; Trelease and Trelease, 1935) have shown that good development of wheat occurs at the pH of this buffer. Similar phosphate buffers have been employed by other workers in manometric respiration studies on tissues of higher plants (Marsh and Goddard, 1939; Goodwin and Goddard, 1940; James and James, 1940). Best germination of rice seeds and growth of young seedlings is reported by Alam (1936) to occur at pH 6.4–6.5. Dastur and Winifred (1938) found best growth of rice in the pH range of 6.4 to 7.0. The importance of the physiological balance of salts is well known and has been amply demonstrated for wheat seedlings by Trelease and Trelease (1926). Ion balance has been taken into consideration in the preparation of substrates in a number of recent respiration studies (Goodwin and Goddard, 1940; Turner, 1938a; James and James, 1940). Several investigators have demonstrated increase in respiratory activity, especially anaerobic activity, in substrates enriched with carbohydrates. The maximum effect in barley seedlings resulted when the sucrose concentration of the buffer was 0.117 molar (Brown and

¹ Received for publication June 6, 1942.

Prepared in the Department of Botany, Columbia University, under the direction of Professor Sam F. Trelease.

Morris, 1890; Barnell, 1937; James and James, 1940).

A temperature of 30°C. was adopted for these tests to insure rapid germination and high respiratory activity of both wheat and rice. Tao (1930) described greatest growth of rice at a temperature close to 35°C. Optimum germination temperature for rice was found by Akemine (1914) to be 30–35°C. Dastur and Desai (1935) selected 30°C. for their respiration studies of rice. Mack (1930) showed that wheat produced carbon dioxide most rapidly at 30°C. while developing for 48 hours in a wide range of O₂ tensions. This temperature was somewhat above the optimum, 25°C., for shoot elongation. Shirk and Appleman (1940) chose 28°C. for their studies of the respiration of wheat in a very early developmental stage (28 to 33 hours). The germination of seedlings, the growth studies, the respiration tests and other experiments reported in the present paper were carried out at 30°C., except where specially noted.

After an hour of pretreatment in the sucrose buffer, 25 wheat seedlings or 30 rice seedlings were individually placed on a layer of glass beads, with their roots submerged in the buffer solution to a depth of 1 to 2 mm., in each respiration vessel. Four or five replicates of the same treatment were tested simultaneously. The beads, by holding the seedlings in position, were found to reduce variation among the replicates. Three cc. of the sucrose buffer, added in each vessel, brought the level to the upper surface of the layer of beads.

For measuring the O₂ uptake and the CO₂ production by the same seedling sample, Barcroft-Warburg manometers were used according to the first method of Dickens and Simer (Dixon, 1934, p. 61–67). The sensitivity of the manometer-vessel systems varied, according to the technique used, from 30 to 55 c.mm. for 1.0 cm. of movement of the manom-

Fig. 1. Respiration vessel. The volume of the closed vessel is approximately 43 cc. The 2.5 cc. side-bulbs, fitted with capillary stoppers, are at an angle of 90° from one another and 45° from the plane in which the vessels are shaken in the bath. Center wells are removable. During flushing with gas, a glass tube is attached to the upper end of the stopper and its open end dips below the surface of the water in the bath. A layer of glass beads covers the bottom of the vessel.

eter fluid. In air (20.8 per cent O₂) 25 intact wheat seedlings consumed about 425 c.mm. of O₂ per hour. The vessels had removable center wells and two side-bulbs fitted with ground-glass capillary plugs (fig. 1). When using gas mixtures with O₂ tensions of 2.5 per cent or higher, CO₂ absorption was accomplished by loading one side-bulb, fitted with a roll of filter-paper, with 0.5 cc. of saturated Ba(OH)₂ and putting 0.5 cc. of 4 N HCl in the other side-bulb. In tests with mixtures containing less than 2.5 per cent O₂ (in which O₂ uptake activity was small in comparison with CO₂ production) both side-bulbs were loaded with Ba(OH)₂ and filter-paper roll, and 0.75 cc. of 4 N HCl was used in the removable center well.

A number of experiments were conducted in which the CO₂ production was determined by means of Warburg's two-vessel direct method (Dixon, 1934, p. 57). The results of such experiments were in good agreement with those in which activity was measured by the technique of Dickens and Simer.

Immediately after the vessels had been loaded with Ba(OH)₂, they were placed in a constant temperature bath maintained at 30±0.02°C. The vessels were connected in parallel to a manifold, and 19 liters of gas mixture saturated with water vapor were flushed through the six-vessel system in 15 minutes. With the aid of a mercury manometer and filter pump, the gas mixtures were prepared by partially replacing the O₂ in normal air with commercial N₂ assayed to be 99.8 per cent. In experiments conducted in complete absence of O₂, the N₂ was prepared by passing the commercial gas through a combustion tube containing 30 cm. of red-hot reduced copper powder.

After being flushed with gas mixture, the closed systems were allowed 10 to 15 minutes to come to the temperature of the bath before the test was started.

During the test the vessels were shaken at a rate of from 100 to 110 complete oscillations a minute through a chord of 3 cm. Uptake of O₂ and evolution of CO₂ were followed, according to the directions of Dixon (1934), over a period of from 45 to 70 minutes, depending upon activity. Immediately after the final readings of O₂ consumption had been taken, the acid was spilled on the substrate and on the tissue, to stop abruptly the respiratory activity. The CO₂ was then released from the BaCO₃ by flushing the alkali bulbs with the acidified substrate. Twenty minutes after the acidification of the Ba(OH)₂, readings were taken of the released CO₂.

After the respiration test, the seedlings were removed from the vessels. Their embryos, including the scutella, were carefully excised from the endosperms and dried to constant weight in an oven at 100°C. Respiratory activities were calculated in the manner described by Dixon (1934). The total embryo weight of the seedlings in each vessel was used in calculating the initial CO₂ production during the preliminary period of equilibration. Original calculation of all activities was carried out on the basis of embryo dry weight.

Since a standard number of wheat or rice seedlings was employed in all respiration tests, it was possible, by means of a conversion factor (total dry weight embryos/number seedlings), to express activities on the basis of units of intact seedlings. Data from 8000 wheat units and 9000 rice units showed that 1.65 milligrams of embryo dry weight were equivalent to one intact wheat seedling, and 0.75 milligram of embryo dry weight was equivalent to one rice seedling.

Growth studies.—Three times the required number of seeds were treated as in the respiration experiments; and after 12 hours, normally developing seedlings were selected for use in experiments on the relation between O_2 tension and growth. Thirty or 35 seedlings were placed on filter-paper moistened with distilled water in a two-quart Mason jar, serving as a growth chamber. The seedlings were allowed to develop in the dark in water-vapor-saturated streams of gas containing from 0.3 to 20.8 per cent O_2 . Six growth chambers, three of wheat and three of rice, were connected in alternate order in a chain. All materials used in the growth chambers were sterilized. Forty liters of commercial N_2 were flushed for 15 minutes through all chains except those supplied 20.8 per cent O_2 ; then all chains, including those with the 20.8 per cent O_2 , were flushed during 20 minutes with 19 liters of the gas to be tested. During the remainder of the growth period, the apparatus was adjusted to a gas flow of 19 liters in 24 hours through each chain.

When the seedlings were 108 hours old, they were removed and fixed in chrom-acetic or 70 per cent alcohol solution. The developed embryos of the group in each chamber were later excised, dried at $100^\circ C.$, and weighed. Increment in dry weight of embryo (i.e., all of the seedling except the endosperm) during the period from 12 to 108 hours was used as a measure of growth.

For germination tests at various O_2 tensions, 100-seed samples of wheat or rice were placed in each chamber of the chain. Germination counts were made at intervals during a period of 72 hours. The results were calculated on a basis of total number of seeds and total number of viable seeds.

In testing the tolerance of wheat and rice seedlings for alcohol, fifteen 12-hour-old seedlings, germinated in the manner described above, were grown in the dark for 96 hours in contact with solutions containing 4 per cent or less, by volume, of ethyl alcohol in distilled water. Six hundred cc., tall-form, spoutless, Pyrex beakers, containing 50 cc. of alcohol solution and lined with two thicknesses of filter paper, served as growth chambers. The seedlings were inserted, between the filter paper and glass, 6.5 cm. above the level of the solutions, and the tops of the beakers were sealed with parafilm. Every 24 hours during a test, the growth chambers were flushed with air, and the alcohol solutions were renewed. All materials used, except the parafilm, were sterilized. Growth measurements were taken as in the experiments on the effect of O_2 tension on the growth of seedlings.

INFLUENCE OF OXYGEN ON GERMINATION.—That crop seeds differ in their capacity to germinate in an environment low in O_2 has been shown in numerous investigations. Crocker (1906) and Shull (1911) reviewed much of the earlier literature on this subject. Morinaga (1926a, 1926b) reported briefly on the germinating capacity of seeds of more than 75 different species of plants and gave detailed results showing that the germination of cattail (*Typha latifolia*) and Bermuda grass (*Cynodon dactylan*) seeds was not inhibited, or was even stimulated, by reducing the O_2 concentration below that in air. He placed wheat seeds in the group incapable of germination under water and cited earlier work showing that rice was able to germinate even in the complete absence of O_2 . Yokoi (1898) and Takahashi (1905) published ample evidence that rice seed is capable of germination under water, in an atmosphere with reduced O_2 concentration, or even in a completely anaerobic environment. More recently, Sasaki (1927) and Edwards (1933) have confirmed the earlier work on rice germination. A decreased O_2 supply—whether existing in the external environment or resulting from the morphological character of the seed—has been considered to have an important influence upon the respiratory activity and germinating capacity of seeds.

Fig. 2. The germination of wheat and rice seeds in relation to O_2 tension. Wheat, broken lines; rice, solid lines.

In the present investigation it seemed desirable to include experiments showing the effects on germination of progressively reduced O_2 tensions. Data were obtained on the rate of germination as well as on the total germination at the end of 72 hours.

Germination involves the resumption of growth by the seed-embryo. In these experiments seeds were regarded as having germinated when any seedling

organ had attained a length of not less than 1.5 mm. By using this criterion, germinated seeds were easily distinguishable by visual inspection of the germinators.

Table 1 gives the results, expressed as percentages of viable seeds, of the germination experiments. The data are presented graphically in figure 2.

It is apparent that reduction of O₂ tension does not significantly reduce germination of rice seeds, whereas progressive reduction of O₂ below 5 per cent produces a rapid decrease in total germination of wheat seeds—no germination at all occurring in the complete absence of O₂. These results are in good agreement with those reported in earlier investigations.

In comparing wheat and rice with respect to rate of germination, we may arbitrarily select a certain percentage of germination—such as 40 per cent—and note in figure 2 the time periods required for this percentage to be reached in the various O₂ tensions by the two types of seeds. It may be seen that the rate of germination of rice is only slightly decreased as the O₂ tension becomes lower. In air 40 per cent of the rice seeds germinated in 23 hours, while in the complete absence of O₂ the time required was increased to only about 30 hours. In wheat 40 per cent germination occurred in air in 18 hours; but a marked decrease in rate of germination resulted when the O₂ tension was decreased. The time needed for 40 per cent germination was 29, 36, and 40 hours, respectively, in 5.2, 2.6, and 1.3 per cent O₂. Wheat seeds were incapable of attaining 40 per cent germination at O₂ tensions below 1 per cent.

INFLUENCE OF OXYGEN ON GROWTH.—In discussing the results of investigations conducted prior to 1900, Pfeffer (1900) showed that growth of aerobic plants is variously affected in different species and organs by decrease in partial pressure of O₂. Since 1900 many conflicting reports on the subject have

appeared. Mack (1930) reviewed much of the important literature dealing with growth and respira-

^a Total weight of 108-hour embryo in air equals 100 percent.

tion of cereal grain crops in early developmental stages. He emphasized the fact that the reaction to a low O₂ supply is dependent upon a complex set of influential variables, including past experience, vigor, current environment, and various counter responses, such as etiolation or respiratory CO₂ output. To obtain evidence on the influence of O₂ on growth, Mack recommended and employed short-interval test periods.

Test periods of short duration were used in the present comparative study of the growth and the respiratory responses of wheat and rice to reduction in O₂ tension. The results of three growth experi-

ments are combined in table 2 and plotted in figures 3 and 4. Three tests, each involving a hundred selected seedlings, were analyzed for each treatment in each experiment. The first two experiments were conducted during the summer, and their results are in good agreement. The third experiment, conducted during the winter, gave similar results, although the absolute growth values were slightly lower, probably because of a somewhat lower temperature. In the first two experiments the increment in dry weight of the embryo from 12 to 108 hours was taken as a measure of growth. In the third experiment the 108-hour weights of the embryo and its parts were used

as the measure of growth; it was not feasible to dissect the 12-hour embryo into its parts.

As the O_2 tension of the environment was progressively decreased, embryo growth of wheat fell off much more rapidly than did that of rice. Considering the increment in both seedlings occurring in air to be normal or 100 per cent, it may be seen that the percentage in rice at any O_2 tension was approximately two or more times as large as in wheat (fig. 3). Rice seedlings were capable of making 15 per cent of normal growth in 0.3 per cent O_2 , while wheat growth was insignificant. It was observed that at this O_2 concentration the length of the shoot of rice was at least 50 per cent of that in air. Macrodissection of shoots of both seedlings grown at the low O_2 tensions revealed that the growth was the result of coleoptile elongation, the plumules having remained undeveloped. Root growth of both seedlings at the lowest O_2 tension tested was almost completely inhibited. The same observation in lesser degree applied to the shoot growth of wheat. In addition, it was apparent that decrease in O_2 tension below 5 per cent had a much more pronounced inhibiting effect upon elongation and lateral development of roots than upon growth of shoots. In view of these observations, it is evident that measurements of growth activity based on shoot length alone, such as were employed by Mack, would not present a complete quantitative picture of the growth reaction, especially in rice seedlings.

A somewhat different measure of the growth resulting in the various treatments may be obtained by considering how many times the weight of the original twelve-hour-old embryos was multiplied during the test period. Growth indices calculated in this manner showed that as the O_2 concentration was decreased to 5 per cent and below, the rate of multiplication of embryo weight decreased at a higher O_2 tension and to a greater extent in wheat embryos than in rice embryos. These two ways of expressing growth—as increment in embryo weight and as multiplication of original weight—yielded results from which similar conclusions may be drawn, in spite of the fact that initially the embryos of rice were only about one-half as heavy as those of wheat.

In the third experiment the growth responses of roots and shoots to decreasing O_2 concentration were noted. The total growth reaction was essentially the same as had been previously observed. In separating the embryo parts, the tissue of the scutellum and transition zone was excised from that of the shoot and root. The results are given in table 3, and they are plotted in figure 4 on a scale of ordinates in which the total weight of the 108-hour embryo in air is considered as 100 per cent. Examination of the curves shows that in wheat seedlings growing in air, root growth is more rapid than shoot growth, whereas in rice seedlings the relationship is reversed. With decrease in O_2 tension, root growth in both seedlings falls off faster than does shoot growth, and the root of wheat is more markedly affected than any other part of either seedling. Of the main growing regions

of the seedlings, rice shoots were least responsive to reduced O_2 tension. There was little or no change in the scutellum-transition zone fraction of either kind of seedling, and so in low O_2 tensions this region constituted the major fraction of the embryo.

In studying the influence of O_2 on the growth of the embryo as a whole as well as on the growth of its components (root, transition zone, and shoot), the use of dry weights resulted in a more accurate picture of the response than would have been obtained by means of a criterion based upon length of embryo or organs, such as was employed by Yokoi (1898) for rice seedlings and by Mack (1930) for wheat seedlings. Although measurements of the linear dimensions of the seedlings or their parts were not made, visual inspection of seedlings at intermediate O_2 tensions showed a shortening and slight thickening of the wheat shoots, accompanied by shortening of primary roots and the development of masses of proliferated root-like tissue where secondary roots would normally have developed. With lowered O_2 tension, where curtailed root growth occurred in rice, the linear growth and the lateral branching were decreased. In other respects these rice roots appeared nearly normal, and they were similar to those diagrammed by Yokoi. While retarded elongation of

Fig. 5. The influence of O_2 tension on the evolution of CO_2 by intact seedlings of wheat and rice. Total CO_2 , respiration CO_2 , and fermentation CO_2 are shown.

rice roots was occurring in response to O_2 reduction, the shoot elongated at an approximately normal rate.

The results of the present study on total embryo development of wheat confirm and amplify the observations reported by Mack (1930). The growth reactions of rice here recorded are in good agreement with those described in less comprehensive studies by a number of investigators, including Yokoi (1898), Nagai (1916), Sadamoto (1926), Sasaki (1927), and Edwards (1933).

RESPIRATION OF INTACT SEEDLINGS.—Most seeds normally germinate and accomplish early development in environments known to contain low O_2 tensions, intermediate between that of normal air and

the completely anaerobic condition. Under reduced O_2 tensions, various types of seeds might be expected to show differences in their aerobic-anaerobic metabolic balance. It is evident that rice seeds are capable of germinating in the absence of O_2 and the seedlings grow well in an atmosphere containing a very low O_2 tension, whereas wheat is unable to germinate or develop under similar conditions. In attempting to explain the marked differences in the ability of various seeds to grow in low O_2 concentrations and the differences in the germination and growth of the wheat and rice seedlings observed in the present studies, it seemed desirable to investigate the influence of variation of O_2 tension on the respiratory activities of these seedlings.

The literature contains many reports of effects of O_2 on the growth or respiratory activity of seedlings of higher plants. Among the earlier papers are those of Pfeffer (1885), Diakonow (1886), and Palladine (1894). These investigators noted that in a very few cases the anaerobic CO_2 output of germinating starchy seeds equalled or even exceeded the aerobic CO_2 output. The early work, largely by German and Russian investigators, on the respiration of young seedlings has been considered in detail in treatises by Palladin (1926) and Kostychev (1927). These studies showed that seedlings of higher plants are capable of maintaining various degrees of CO_2 evolution over short periods of time when they are subjected to low O_2 tensions or even to completely anaerobic conditions. Wheat was placed in the group having an average or low anaerobic activity. In a detailed study of the higher plants, Stich (1891) reported that rice seedlings were capable of high CO_2 outputs at O_2 tensions below that in air. Mack (1930) carried out a comprehensive investigation of CO_2 evolution and simultaneous growth response of wheat seedlings. Dastur and Desai (1935) studied changes in respiratory activity and carbohydrate reserves in rice seedlings from germination to the ten-day stage. James and James (1940) made a thorough study of the course of respiration and metabolic change occurring in barley seedlings. In the three studies just mentioned, macro-methods were used to follow the respiratory activities of seedlings exposed continuously, from the beginning of germination, to controlled gas environments. The more sensitive manometric technique was used by Shirk and Appleman (1940) and Merry and Goddard (1941), to follow the O_2 uptake or CO_2 output of seedlings of wheat or barley. A number of studies on aerobic respiration have been reported in which either the evolution of CO_2 or the uptake of O_2 was observed, and some papers have dealt with the anaerobic CO_2 output in the absence of O_2 . A complete picture, however, of changes in the respiratory complex— aerobic and anaerobic activities—that occur in response to decreasing O_2 tension cannot be obtained from measurements of CO_2 output alone.

In the present investigation manometric measurements, during short intervals of time, were made of the effects of O_2 tension on the respiratory activities

of intact wheat and rice seedlings germinated in air and then treated with the experimental gaseous environment immediately prior to and during the actual period of the tests. Measurements of both O_2 uptake and CO_2 output, during the same period, were made according to the method of Dickens and Simer.

The results of the gas-exchange measurements are shown in table 3 and figures 3 and 5, in which smoothed curves have been drawn in solid lines to show the trend of the experimentally determined points, each of which represents the average of four or five separate determinations. In 20.8 per cent O_2 (air) the average activity of rice seedlings, as shown by CO_2 evolution, was found to be 87 per cent of the average of wheat seedlings on the basis of dry weight of embryos. To facilitate comparison of the experimental data, the curves in all cases have been plotted for the activity of a number of seedlings (wheat, 6.4; rice, 13.3) calculated to produce 100 c.mm. of CO_2 per hour in 20.8 per cent O_2 .²

Inspection of the curves of figure 3 for O_2 consumption reveals the following relations: The O_2 intake by rice is less rapid than that by wheat over the range of O_2 tensions in which tests were conducted. With decrease in O_2 tension, the O_2 uptake curve for wheat falls rapidly and roughly parallels the curve for growth. In rice the relation is very different: As the O_2 tension is decreased, the growth curve remains relatively high in spite of a rapid and continuous decrease in the O_2 intake.³

In spite of lower aerobic respiratory activity, rice seedlings were able to make more nearly normal amounts of growth than wheat seedlings in O_2 tensions lower than that of air or in the complete absence of O_2 . To account for the difference in growth response, we might assume greater utilization by rice of the energy liberated in respiration; but such an assumption is unsupported by experimental evidence. It seems more logical to seek an explanation of the difference in growth response in a difference in the fermentation (anaerobic) activities of the two types of seedlings.

Figure 5 shows not only total evolution of CO_2 , but also its components—respiration CO_2 and fer-

² The values for O_2 uptake activity of wheat seedlings in air are slightly lower than those obtained by Curry, Pratt, and Trelease (1935) for similar material; but, probably owing to differences in stage of seedling development, they are five to seven times as great as those reported by Brown and Goddard (1941) and by Shirk and Appleman (1940).

³ During the course of these experiments, a large number of tests were made with NaN_3 (sodium azide) in the substrate. Approximately 70 per cent of the normal activity in wheat and 50 per cent of the normal activity in rice was inhibited by 10^{-4} M NaN_3 . Significant photo-reversible inhibition of the activity of both seedlings was observed at 20°C. in a 90 CO_2 /10 O_2 gas mixture compared with a 90 N_2 /10 O_2 mixture. These results indicate that respiration in these seedlings is at least partially dependent upon cytochrome oxidase. From similar evidence it has been concluded that this enzyme is probably responsible for a large fraction of the respiration of barley seedlings (Merry and Goddard, 1941) and of wheat embryos (Brown and Goddard, 1941).

TABLE 3. *Respiratory activities of intact wheat and rice seedlings at various O₂ tensions. (C.mm./hour/standard sample: Wheat 6.4 seedlings, rice 13.3 seedlings.) R.Q. values in air: Wheat 0.92, Rice 0.96.*

mentation CO₂. In preparing these curves, two basic assumptions were made: The first assumption was that in 20.8 per cent O₂ (air) all the CO₂ production of the seedlings was due to respiration (aerobic activity)—in other words, that in this O₂ tension no fermentation (anaerobic activity) occurred. The second assumption was that in all O₂ tensions the aerobic respiratory quotient (R.Q. = CO₂/O₂) was the same as it was in air.

The assumption that in 20.8 per cent O₂ all the activity is due to respiration (and only a negligible amount due to fermentation) is supported by many investigations on normal tissues of higher plants (Blackman, 1928; Kostychev, 1931; Turner, 1937; Marsh and Goddard, 1939; Merry and Goddard, 1941). It is well known that wheat and rice seedlings

contain starchy reserves which are converted to sugars and are then aerobically oxidized according to the general equation: $C_6H_{12}O_6 + 6 O_2 \rightarrow 6 CO_2 + 6 H_2O$. This results in a theoretical R.Q. (CO₂/O₂) of 1, which has been approximated in many studies (Tao, 1930; Dastur and Desai, 1935; Rianga, 1938; James and Bunting, 1941). In air the R.Q.'s of wheat and rice seedlings, both intact and excised, in the large number of tests and control determinations conducted in the present study did not vary markedly from 1, and so indicate aerobic respiration of hexose sugar. In tests made in 50 per cent O₂ the R.Q. for wheat seedlings was found to be 0.80, and for rice seedlings 0.85, whereas in air the R.Q.'s were 0.92 and 0.96, respectively. The lowering in the R.Q. resulted from a slight decrease in

CO₂ output and a slight increase in O₂ uptake. These results indicate that a small but probably negligible amount of fermentation may have occurred in air, possibly because of a slight limitation of O₂ diffusion. R.Q. values of 1 might result from combinations of various reactions involving aerobic and anaerobic respiration of heterogeneous substrates containing sugars, proteins, or fats, and non-enzymatic, non-respiratory oxidations (Goodwin and Goddard, 1940). However, under the conditions of the present experiments and in view of the findings of other workers, it seems reasonable to assume that the observed R.Q. values of approximately 1 for seedlings of wheat and rice in air represent chiefly aerobic hexose catabolism.

The second basic assumption made in preparing the curves of figure 5—namely, an essentially constant R.Q. for respiration (aerobic activity) at all O₂ tensions—seems entirely logical in the absence of any evidence indicating that a different type of substrate is consumed in respiration at lower O₂ tensions. The assumption of a constant R.Q. for aerobic respiration has been made in many similar investigations.

Continuing with the description of the method of calculating the data presented in figure 5, it is evident that knowing the respiratory quotient, the measured O₂ absorption, and the CO₂ evolution over the range of O₂ tensions, it is possible to calculate the amounts of respiration CO₂ and fermentation CO₂ for any O₂ tension as follows:

C.mm. O₂ × respiratory quotient = c.mm. respiration CO₂.

C.mm. total CO₂ — c.mm. respiration CO₂ = c.mm. fermentation CO₂.⁴

Applying this method to the smoothed curves for total CO₂ (fig. 5) and O₂ (fig. 4), the curves for fermentation CO₂ shown by broken lines in figure 5 were obtained.

From figure 5 it may be seen that as the O₂ tension decreases, the experimentally determined curve for total CO₂ output of wheat falls, whereas there is a rise in the corresponding curve for rice.

The greater CO₂ evolution in the absence of O₂ than in air is comparable to what was observed in *Vicia faba* in earlier studies (Diakonow, 1886) and is more pronounced than the reaction noted in rice by Stich (1891). Morinaga (1925) and Dastur and Desai (1935) found high anaerobic CO₂ output in rice seedlings subjected to relatively long anaerobic pretreatment, but this did not exceed the aerobic CO₂ output. Differences in experimental technique

⁴ Difficulties would probably be encountered if attempts were made to differentiate quantitatively between respiration and fermentation in complex heterogeneous seedling tissues by use of respiratory block techniques. The results might be complicated by general toxic effects of the respiratory inhibitors on the protoplasm, and they might depend upon the character of the heterogeneous tissues studied and upon the point at which the common pathways of respiration and fermentation processes branch. Some aspects of this problem have been treated by Turner (1937, 1938b), Marsh and Goddard (see Burk, 1939, p. 457), and James and Bunting (1941).

—i.e., in substrate, pretreatment, material, duration of the test, or method of analysis of gas exchange—may well account for the differences in activities observed in various studies. The rate of aerobic CO₂ output of wheat seedlings in air noted in the present experiments was identical with that observed by Mack (1930) for seedlings of the same age and at the same temperature.

The curves for CO₂ produced in respiration are similar in form to the O₂ activity curves of figure 3 from which they were calculated; wheat shows higher respiratory activity than rice.

Inspection of the fermentation curves of figure 5 shows about 2.7 times as great activity in rice as in wheat. As the O₂ tension decreases from 10 to 0 per cent, the fermentation in rice increases rapidly, until the CO₂ output by fermentation in 0 per cent O₂ reaches 150 per cent of the total CO₂ evolution in air. With corresponding decrease in O₂ tension, the increase in fermentation in wheat is much more gradual, and in the complete absence of O₂ the CO₂ output attains a level only 57 per cent as high as the total CO₂ output in air. This observation is in complete agreement with that of Karlsen (1925).

Approximate anaerobic CO₂/aerobic CO₂ ratios (total CO₂ in N₂/total CO₂ in air) for wheat and rice are 0.5 and 1.5, respectively. For wheat this value is the same as values found by many earlier investigators. The value of the ratio in rice is extremely high and far above those reported for most other seedlings or tissues of higher plants. In *Vicia* seedlings Diakonow (1886) found a ratio of 1.5, and others have obtained values near unity for *Vicia* and *Pisum*. More recently, Marsh and Goddard (1939) found that carrot roots had a ratio of 1.2.

Anaerobic CO₂/aerobic CO₂ ratios and Meyerhof quotients greater than 1/3 have been interpreted as indicating the operation of the Pasteur effect—that is, O₂ inhibition of fermentative processes (Dixon, 1937; Turner, 1938b; Burk, 1939; Marsh and Goddard, 1939; Merry and Goddard, 1941). The following formula was used to calculate Meyerhof quotients at the various O₂ tensions:

$$\text{Meyerhof quotient} = \frac{\text{c.mm. fermentation CO}_2 \text{ in N}_2 - \text{c.mm. fermentation CO}_2 \text{ at given O}_2 \text{ tension}}{\text{c.mm. respiration CO}_2 \text{ at same O}_2 \text{ tension}}$$

This method is essentially the same as that described by Dixon (1937) and Burk (1939).

Meyerhof quotients, shown in table 3, for seedlings at O₂ tensions above 0.3 per cent are from 1.5 to 2.0 for rice and 0.2 to 0.5 for wheat. The quotients for rice (comparable in magnitude to values reported for yeast) and those for wheat at certain O₂ tensions, together with the anaerobic CO₂/aerobic CO₂ ratios described, indicate that the Pasteur effect occurs in both seedlings and is of a very high degree in rice seedlings.

With increase in the O₂ tension, the values of the F/R ratio (ratio of fermentation to respiration where O₂ is present, 0.3 per cent or higher) range from 9 to 0 for wheat and from 53 to 0 for rice.

TABLE 4. *Respiration of excised embryos and endosperms at various O₂ tensions. All activities are expressed as cmm./hr./standard sample. R.Q.'s—Wheat: Total, 0.88; Embryo, 0.90; Endosperm, 0.82. Rice: Total 0.90; Embryo, 0.88; Endosperm, 0.96.*

RESPIRATION OF EXCISED PARTS.—Having determined the respiration and fermentation of intact wheat and rice seedlings over a range of O_2 tensions, it seemed desirable to repeat this study on excised embryos (all of the intact seedling except the endosperm) and on endosperms, since the growth that was measured was that of the embryo, which occurred at the expense of food stored in the endosperm.

A technique almost identical with that employed for the intact seedlings was used for the separated parts. The only difference in the procedure was that the embryos were carefully dissected from the endosperms after the seedlings had been removed from the germinators, and then pretreatment was given to each of the excised parts of the seedlings.

The results of these excision tests are given in table 4 and figures 6 and 7. To facilitate comparison, the data are expressed in terms of seedling samples of such size that the sum of the CO_2 output of the excised embryos and endosperms is equal to 100 c.mm. per hour in air. This amount of activity was shown by 6.65 excised wheat seedlings and by 12.50 excised rice seedlings. All activities are expressed in terms of samples of the same size.

Since the standard samples for intact seedlings was 6.4 for wheat and 13.3 for rice, excision appears to have caused a 7 per cent decrease in the total CO_2 activity (embryo + endosperm) of wheat in air and a 6.5 per cent increase in that of rice seedlings in air. In response to excision, wheat O_2 uptake remained constant or increased very slightly, while excision resulted in a 10 per cent increase in O_2 uptake of rice.

In general the curves of figures 6 and 7 show the same trends as those of figure 5 for intact seedlings, and so it is evident that excision has produced no pronounced change in the over-all activity of the seedling parts.

From the curves of figure 6 and the values in table 4a for wheat it may be seen that approximately 80 per cent of the total (embryo + endosperm) activities are in the embryo over the entire range of O_2 tensions.

The striking difference between the respiratory quotient (R.Q.) of the excised embryo (1.0) and that of the endosperm (0.35) observed in barley by Merry and Goddard (1941) and noted in lower degree in endosperms (reduction to 0.5 or 0.6) in most of the tests conducted by Stoward (1908) was not found in wheat or rice in the present studies. For wheat, average values for the respiratory quotient in air were as follows: total, 0.88; embryo, 0.90; endosperm, 0.82. For rice they were: total, 0.90; embryo, 0.88; endosperm, 0.96. Enrichment of the substrate with sucrose, difference in temperature, or difference in the type of seedling and phase of development may have been controlling factors. The respiratory quotients for wheat and rice embryos in air are similar in magnitude to those noted in studies on barley (Stoward, 1908; James and James, 1940; Merry and Goddard, 1941).

The rate of CO_2 output by excised wheat endosperms and its proportion to total seedling CO_2 output in N_2 as well as in air were comparable to observations on barley endosperms by Barnell (1937); O_2 uptake by wheat endosperms was approximately the same (0.95 times as great) as that observed by Merry and Goddard in barley endosperms.

The relationships of fermentation and respiration to decrease in O_2 tension are essentially the same for the excised seedling parts and their total as for intact wheat seedlings.

Fig. 6-7.—Fig. 6 (above). CO_2 evolution by excised wheat seedlings. Effects of O_2 tension on respiration CO_2 , fermentation CO_2 , and total CO_2 evolution of excised wheat germs (embryos) and endosperms.—Fig. 7 (below). CO_2 evolution by excised rice seedlings. Effects of O_2 tension on respiration CO_2 , fermentation CO_2 , and total CO_2 evolution of excised rice germs (embryos) and endosperms.

It may be seen from the curves of figure 7 (plotted from table 4) for excised embryos and endosperms of rice seedlings that in air the embryo activity of rice accounts for about 65 per cent of the total activity (embryo + endosperm), whereas the embryo activity of wheat (fig. 6) makes up about 80 per cent of the total activity. The rice embryo (0.75 mg.) makes up $1/18.5$ of the total weight of the seed, while the wheat embryo (1.65 mg.) makes up $1/15$ of the total weight of the seed. (These figures are averages for 1530 rice embryos and endosperms and 1050 wheat embryos and endosperms.) Therefore, when the relative proportions of the total seedling weight contributed by the excised embryos and endosperms are taken into consideration, it appears that the relation of embryo activity to total activity is the same in rice as in wheat ($65 \times 18.5/15 = 80$).

The distribution of respiratory activity observed in embryos and endosperms of wheat and rice agrees with that reported in wheat by a number of earlier investigators (see Lyon, 1928). The data of Stoward (1908) show that the embryo contributed a smaller fraction of the total CO_2 output of barley seedlings than was observed in these studies on wheat and rice. Since Stoward's data show a lower total CO_2 output, the difference could be due to lower activity in his barley embryos, respiration of which was measured in non-enriched substrate.

The response of the excised rice endosperms to decreasing O_2 tension was similar to that observed for wheat endosperms.

Both intact rice seedlings and excised rice seedlings showed a marked rise in CO_2 output as the O_2 tension decreased from 10 per cent to between 1.3 and 0.7 per cent. The form of the curve for total activity was determined mainly by embryo activity. The percentage of total activity carried on by the embryo increased from about 65 per cent at an O_2 tension of 10 per cent to approximately 85 per cent at an O_2 tension of 1.3 per cent.

Endosperm respiration gradually decreased to zero as the O_2 tension decreased to zero. Endosperm fermentation increased gradually as the O_2 tension decreased until, in N_2 , it amounted to about 30 per cent of the total CO_2 activity in air or in N_2 .

From the results thus far presented, we may conclude that at low O_2 tensions rice seedlings are superior to wheat seedlings in the degree to which they are capable of carrying on normal activities. With restricted O_2 supply, rice is more capable than wheat of germinating and maintaining growth. Rice can carry on these activities in very low O_2 concentrations, or even in the absence of O_2 , because it possesses a fermentation system which functions strongly enough to compensate for its decreased respiration. In contrast, wheat, which exhibits a stronger aerobic activity than rice at all O_2 tensions, is unable to germinate or grow at low O_2 tensions at rates nearly approaching those in air (a more nearly normal environment for wheat) because the increase in fermentation is not sufficient to compensate for

the reduction of respiration brought about by the decrease in the supply of O_2 .

The outstanding difference between the curves for excised seedlings of rice and those for intact seedlings is the fall in total CO_2 and fermentation CO_2 at O_2 tensions below 1.3 per cent. The total CO_2 represented chiefly embryo fermentation, and decreased markedly below an O_2 tension of 1.3. At an O_2 tension of 1.3 per cent the embryo produced 85 per cent of the CO_2 of fermentation and 80 per cent of the total CO_2 . In N_2 (zero O_2) the embryo produced 70 per cent of the CO_2 of fermentation and 70 per cent of the total CO_2 .

Below an O_2 tension of 1.3 per cent there is a conspicuous and apparently significant decrease in total CO_2 output, in total fermentation, in total embryo CO_2 output, and in embryo fermentation, while a slight but questionable increase occurs in endosperm CO_2 output.

Further experiments were conducted on intact rice seedlings in O_2 tensions below 1.3 per cent to check the results obtained (fig. 5, table 3). The results of these experiments gave no indication that a decrease, such as that observed in the CO_2 output of excised embryos, occurred in the activity of intact rice seedlings below an O_2 tension of 1.3 per cent. The reason for the decrease in total CO_2 output of excised rice embryos is not at once evident.

A possible explanation of the pronounced peak at an O_2 tension of 1.3 per cent in the curves for fermentation and total CO_2 output by rice embryo and seedling (fig. 7) may be formulated by considering the possibilities of the interaction of the toxicity of end-products of fermentation, the resynthesis of products of fermentation, and the Pasteur effect. It has been shown for rice (Sawa, 1903) and wheat (Karlsen, 1925) that fermentation end-products are toxic in various degrees. Meyerhof quotients and anaerobic CO_2 /aerobic CO_2 ratios indicate the operation of a strong Pasteur effect in rice. Resynthesis of fermentation products when O_2 was introduced into anaerobic systems which had high Meyerhof quotients was shown by Meyerhof (Meyerhof, 1925; see Burk, 1939).

The full potentialities of the fermentation system of excised rice embryos are not attained at O_2 tensions below 1.3 per cent because of retardation brought about by toxic products of the fermentation. As the O_2 tension rises from 0 per cent, increased respiration could oxidize some of the intermediate and end-products of fermentation.

Therefore, the combined effects of respiration and resynthesis could remove toxic fermentation products and allow fermentation, as indicated by CO_2 evolution, to progress more rapidly with increasing O_2 tension. However, at the same time the increasing O_2 tension produces a Pasteur effect (O_2 inhibition of the fermentative processes) which results in a decrease in CO_2 output by fermentation. The observed CO_2 curves could, therefore, be considered to represent the interaction of three effects of increasing O_2 ; the first two effects are initially strong-

est and decrease in strength, while the third effect is absent in pure N_2 and increases in strength as the O_2 tension rises. Above an O_2 tension of 1.3 per cent the Pasteur effect predominates and fermentation progressively decreases.

In calculating Meyerhof quotients, it is assumed that the fermentation going on in these seedlings at low O_2 tensions is of the alcoholic type. That alcoholic fermentation occurs in wheat and similar seedlings was shown by many of the earlier studies reviewed by Palladin (1926) and Kostychev (1927). More recently, the anaerobic activity in seedlings of cereal grains and various tissues of the higher plants has been shown, or sometimes merely assumed, to be alcoholic fermentation similar to that occurring in yeast (Haas and Hill, 1929; Kostychev, 1931; Dixon, 1937; Turner, 1937, 1938a, 1938b; Burk, 1939; Marsh and Goddard, 1939; Merry and Goddard, 1941). Most investigators have assumed that alcoholic fermentation is the predominant type of anaerobic respiratory activity in tissues of the higher plants. It should be borne in mind, however, that in plant tissues the ratio C_2H_5OH/CO_2 in fermentation does not always equal 1, and that other types of fermentation may be present. The recent investigations by Hohl and Joslyn (1941a, 1941b), as well as earlier studies on yeast fermentation in various media, have indicated that even in yeast—where alcohol is the main non-gaseous end-product of the fermentation—significant amounts of lactic acid or, to a lesser degree, formic acid are produced. It is evident that fermentation may involve a complex set of processes and may result in end-products of various types.

Since there is rather general agreement that alcoholic fermentation is typical of tissues of higher plants, and since it has been shown in many investigations that hexose enrichment of the substrate results in a C_2H_5OH/CO_2 ratio characteristic of alcoholic fermentation, it seems safe to consider that the fermentation occurring in the seedlings of this study, which received carbohydrate enriched substrates, was chiefly of the alcoholic type.

HEXOSE UTILIZATION.—The curves of figure 8, showing relative hexose utilization by intact seedlings, have been drawn from the smoothed curves of figure 5 by assuming that respiration is expressed by the equation $C_6H_{12}O_6 + 6 O_2 = 6 CO_2 + 6 H_2O$ and that fermentation is represented by the equation $C_6H_{12}O_6 = 2 CO_2 + 2 C_2H_5OH$. Relative rates of hexose consumption were, therefore, calculated by dividing respiration CO_2 (in c.mm. per hr.) by 6 and fermentation CO_2 by 2. All the curves represent the relative hexose destruction by a number of seedlings (wheat, 6.4; rice, 13.3) which in air would be capable of producing 100 c.mm. of CO_2 or of consuming 16.7 hexose units per hour.

With decrease in O_2 tension, consumption of hexose increases in both types of seedlings, but the change is much more pronounced in rice than in wheat. At O_2 tensions below 5.2 per cent, intact rice seedlings use up respiratory reserves from 3.5 to 4.6

times as rapidly as in air, while wheat seedlings (in which fermentation is relatively weak) use up their reserves about 1.7 times as rapidly as in air.

A marked Pasteur effect (or O_2 inhibition of fermentative processes) is indicated for rice and a much weaker effect for wheat. Dixon (1937) and Burk (1939) have presented excellent discussions of the Pasteur effect, which involves the action of O_2 in diminishing the rate of carbohydrate destruc-

Fig. 8-9.—Fig. 8 (above). The relation between O_2 tension and relative hexose utilization by intact wheat and rice seedlings (calculated from CO_2 evolution).—Fig. 9 (below). The effect of O_2 tension on the energy released by intact wheat and rice seedlings (calculated from CO_2 evolution).

tion and in suppressing the accumulation of alcohol or other products of fermentation. When the Pasteur effect operates, introduction of O_2 into an anaerobic system may be regarded as preserving hexose reserves that would be destroyed in the absence of O_2 . The number of hexose molecules thus conserved per hexose molecule consumed in respiration may be calculated from values read from the curves of figure 8 by means of the following computation: The total hexose used at any O_2 tension is subtracted from the total hexose used under anaerobic conditions, and the resulting difference (representing the total saving in hexose) is divided by the hexose used in respiration at the same O_2 tension. (The same result is obtained by a computation from the Meyerhof quotient, previously defined, by the use of the following formula: $3 \times M.Q. - 1.0$.) Indices of the Pasteur effect on hexose conservation, calculated in this manner, are summarized in the following tabulation:

O_2 tension	Hexose molecules preserved per hexose molecule used in respiration	
	In rice	In wheat
0.3	4.9	0.3
0.7	4.2	(-0.3)
1.3	4.5	(-0.2)
2.6	4.7	(-0.2)
5.2	4.8	0.1
10.4	4.2	0.4
20.8	3.6	0.7

It is evident that rice seedlings exhibit a pronounced Pasteur effect. For every hexose molecule used in respiration approximately 4 hexose molecules that would be destroyed in the absence of O_2 are preserved as respirable substrate. In contrast, wheat seedlings show little or no conservation of hexose in the presence of O_2 . Although these results, based upon gas exchange, strongly indicate the operation of the Pasteur effect in rice seedlings, it would be desirable to verify them by means of direct measurements of loss of carbohydrate.

In addition to serving as respiratory substrate, sugar is utilized in the growth of the seedling embryo. In this connection we may note the results obtained by Barnell (1937) and by Terroine, Bonnet, and Joessel (1924) on the "utilization coefficients" of barley and rice growing in air. Barnell found that in air approximately 64 per cent of the total hexose made available to the embryo by translocation from the endosperm was used in growth by barley embryos, and Terroine *et al.* reported that about 60 per cent was used by rice seedlings. The latter workers also reported that in air little or no difference was to be found between seeds having endosperms of similar chemical composition; and, in regard to the chemical nature of seed reserves, they stated that starchy seeds had relatively low utilization coefficients.

ENERGY RELATIONSHIPS.—The influence of O_2 tension on the energy released in fermentation and

respiration is shown in the graphs of figure 9. These were prepared from the data of figure 8 by multiplying the hexose consumed in respiration by 6.74 and that consumed in fermentation by 0.26, these figures representing the number of kilogram-calories of heat energy liberated by 0.01 gram-molecule of hexose (Kostychev, 1927; Haas and Hill, 1929). As in the preceding figure, all the curves of figure 9 show the activity of standard samples of intact seedlings (6.4 wheat seedlings, 13.3 rice seedlings). In air these samples would be able to produce 100 c.mm. of CO_2 per hour, or consume 16.7 hexose units, or release 112.4 energy units.

With a reduction in O_2 tension, there is a rapid decrease in rate of total energy liberation, so that under completely anaerobic conditions the rate in rice is $1/6$ that in air and the rate in wheat is $1/15$ that in air. It may be seen that as the O_2 tension is decreased, the total energy released by wheat remains greater than that by rice until an O_2 tension of 0.7 per cent is reached; below this, the total energy of rice drops less rapidly than that of wheat. Fermentation energy becomes greater than respiration energy in rice below an O_2 tension of 1.3 per cent and in wheat below an O_2 tension of 0.3 per cent.

Evidence from many sources points to the conclusion that release of energy is necessary in order that growth may occur. This relationship is indicated by the fact that the decrease in growth of both seedlings roughly paralleled the decrease in total energy liberated in respiration and fermentation. The correlation between growth and energy release is much closer in wheat than in rice. With reduction in O_2 tension, growth of rice remains relatively rapid in spite of a marked decrease in the rate of total energy liberation. Wheat sets free total energy more rapidly than rice above an O_2 tension of 0.7 per cent, and yet even at 5.2 per cent O_2 its growth rate (relative to that in air) is much lower than that of rice.

Throughout the range of low O_2 tensions, where rice exhibits greater growth than wheat, it also liberates more energy in fermentation. These relationships suggest the possibility that, in promoting growth, the energy released anaerobically in fermentation is more efficiently used than the energy liberated in oxidative respiration.

RELATION OF ALCOHOL TO GROWTH AND RESPIRATION.—The experiments described in the preceding sections of this paper show that rice seedlings exhibit a functional fermentation system about 2.5 times as strong as that shown by wheat seedlings and at low O_2 tensions rice seedlings accomplish approximately twice as much growth as wheat seedlings (growth is expressed as percentage of the normal growth made in air). Nevertheless, the possibility exists that the fermentation system may be potentially as strong in wheat seedlings as in rice seedlings. The greater activity of rice than of wheat could result if the fermentation systems of the two

types of seedlings were potentially equal, but if other factors, such as accumulation of toxic metabolic products and difference in degree of tolerance of products in the two seedlings, operated in such a manner as to allow a higher functional respiratory metabolism in rice seedlings than in wheat seedlings.

It has been noted that alcohol is produced by higher plants when they are supplied with a hexose substrate under anaerobic conditions. The production of alcohol by rice was established by Takahashi (1903, 1905), and studies by Sawa (1903) and Nagai (1916) have shown that rice seedlings are capable of growth on a substrate containing dilute ethyl alcohol. Karlsen (1925) found that ethyl alcohol in low concentration inhibited both fermentation and respiration in wheat seedlings, and Gray (1941) noted that different strains of yeast vary in their alcohol tolerance and differ with regard to the minimum concentration of alcohol needed to inhibit fermentation.

Ludwig *et al.* (1941) have recently confirmed the finding that alcohol is produced anaerobically by tissues of higher plants similar to those employed in the present studies and that, when hexose substrate

is supplied, CO₂ and C₂H₅OH are produced approximately according to the principal reaction in alcoholic fermentation of hexose. By means of manometric and chemical tests, they also showed utilization of alcohol as a respiratory substrate by roots of various legumes, oats, and maize.

In an attempt to determine whether or not differences exist between wheat and rice seedlings with respect to alcohol tolerance and utilization, tests of growth and respiration were conducted with alcohol supplied to the seedlings in various concentrations. A summary of these experiments appears in table 5. The results indicate a slight superiority of rice seedlings over wheat seedlings in ability to grow in alcohol solutions containing up to 2 cc. of ethyl alcohol in 100 cc. of solution. Comparing root and shoot reaction in the seedlings, it is seen that rice shoots showed greatest tolerance of alcohol, making most nearly normal growth increment. Rice roots were less tolerant of alcohol than rice shoots but more tolerant than shoots or roots of wheat.

The data on respiration are not extensive enough to warrant treatment comparable in detail to that used by Ludwig *et al.* However, considering the re-

actions for the complete aerobic oxidation of hexose and of alcohol to be

a decrease in the R.Q. of aerobic respiration below unity, when alcohol was present in the substrate in addition to hexose, would strongly suggest that alcohol, as well as hexose, was being utilized as oxidation substrate.

From table 5 it may be seen that both wheat and rice gave indications of a small progressive decrease in the R.Q. as alcohol was added to the medium in increasing amounts. The decrease in R.Q. was not so great as that reported in the more extensive studies of Ludwig *et al.* In the latter studies the decrease in O_2 uptake was much less than the decrease in CO_2 output when alcohol was added in increasing amounts; this indicated a relatively high tolerance of the oxidation system for alcohol. In the tests on wheat and rice seedlings supplied with alcohol, the reduction in CO_2 output was only slightly greater than the reduction in O_2 uptake, and so the R.Q.'s of wheat and rice seedlings did not show decreases comparable in degree to those observed by Ludwig *et al.* in roots of oats and corn, and they did not indicate so much alcohol oxidation. Differences in concentration of hexose in substrate, length of test period, methods, and tissue could account for the difference in degree of reduction of the R.Q. On the basis of the present tests, it appears that the respiratory activities of wheat and rice seedlings respond in similar degree to alcohol, while the growth of the seedlings indicates a slightly higher tolerance of alcohol by rice than by wheat. This relationship could favor a higher functional activity of the fermentation system in rice than in wheat.

SUMMARY

Comparative studies of growth and respiratory activities in seedlings of winter wheat (*Triticum vulgare*) and of lowland rice (*Oryza sativa*) were made at O_2 tensions ranging from 0 to 20.8 per cent. The rate and extent of germination were recorded over a 72-hour period, and growth of seedlings initially 12 hours old was determined for a 96-hour period; in these tests the seedlings were kept on moist filter paper in chambers continuously flushed with gas. Manometric measurements of the gas exchange occurring in seedlings with roots 6 mm. long were conducted according to the technique of Dickens and Simer. The seedlings were provided with a phosphate buffer (pH 5.8) containing 0.117 molar sucrose.

In the absence of O_2 the germination of rice seeds was reduced less than 10 per cent below that in air and was accomplished at more than half the normal rate. No germination of wheat occurred under similar conditions. Significant reduction in the extent and rate of germination of wheat occurred when the O_2 tension was lowered to 5 per cent, and consider-

ably less than half of normal germination resulted in O_2 concentrations below 1 per cent.

At O_2 tensions of 5 per cent or less, rice seedlings made approximately twice as much growth as wheat seedlings (on the basis of increment in dry weight of embryo in air). Reduction in O_2 tension inhibited roots of both seedlings more than shoots, and it had least effect on rice shoots.

The results of the manometric measurements of gas exchange showed that when the respiration rate was expressed in terms of CO_2 evolved per mg. of dry weight of embryo per hour, intact rice seedlings had 87 per cent as great activity in air as wheat seedlings. Per seedling, however, the CO_2 output of rice in air was 48 per cent as rapid as that of wheat in air.

With decrease in O_2 tension from 20.8 to 0 per cent, the rate of O_2 uptake decreased similarly in both kinds of seedlings, but it remained higher in wheat than in rice over the range of O_2 concentrations.

Oxygen uptake of both seedlings was partially inhibited by sodium azide and carbon monoxide, thus indicating at least partial dependence upon cytochrome oxidase.

In the complete absence of O_2 , rice seedlings evolved CO_2 1.5 times as rapidly as in air, whereas wheat seedlings under similar conditions gave off CO_2 only about 50 per cent as rapidly as in air.

It may be concluded that the superiority of rice over wheat in ability to germinate and grow in very low O_2 concentrations is dependent upon the possession by rice of a highly functional fermentation system that more than compensates for a respiration system that is even weaker than that of wheat.

Meyerhof quotients calculated from the gas exchange over the range of O_2 tensions were from 1.5 to 2.0 for rice seedlings and from 0.2 to 0.5 for wheat seedlings. These quotients pointed to a strong Pasteur effect in rice and a very weak effect in wheat. Calculations indicated that for every hexose molecule used in respiration by rice seedlings, approximately 4 hexose molecules that would have been destroyed in the absence of O_2 were preserved as respirable substrate.

With reduction in O_2 tension there appeared to be a rapid decrease in the rate of total energy liberation, so that under completely anaerobic conditions the rate for rice was 1/6 that in air and the rate for wheat was 1/15 that in air.

A consideration of gas exchange indicates that in the range of low O_2 concentrations, where rice exhibited greater germination and growth than wheat, it also liberated more energy in fermentation. The possibility is suggested that, in promoting growth, energy released anaerobically in fermentation may be more efficiently used than the energy liberated in oxidative respiration.

In studies of excised parts of wheat and rice seedlings, it was found that from 65 to 85 per cent of the total CO_2 output at any O_2 tension was contributed

by the embryo. The endosperm in rice made up a larger fraction of the weight of the seed than in wheat, and it accounted for a correspondingly greater percentage of the total CO_2 evolution.

Growth studies showed that rice seedlings were more tolerant of alcohol than wheat seedlings. Some utilization of alcohol as a substrate for aerobic res-

piration was observed in both seedlings. Some of the implications as to substrate utilization, energy release and utilization, and effects of metabolic products are briefly discussed.

VASCULAR DIFFERENTIATION IN THE VEGETATIVE SHOOT OF LINUM. I. THE PROCAMBIUM¹

Katherine Esau

THE PRESENT paper is the first of two articles dealing with the vascularization of the vegetative shoot apex of *Linum perenne* L. Although the course of development of the first xylem in the shoots of seed plants is rather well understood, the information on the pattern of differentiation of the procambium and the first phloem is very scanty (see Esau, 1938, 1939, 1943). The origin of the first vascular meristem in the shoot apex is receiving some attention from workers who are concerned with the organization of the apical meristem and with foliar histogenesis (Boke, 1940, 1941; Cross, 1942; Cross and Johnson, 1941; Satina and Blakeslee, 1941). Then there are studies which attempt to analyze the delimitation of the vascular system in relation to the early differentiation of the axis as a whole (Helm, 1931; Louis, 1935; Kaplan, 1937). Finally, Priestley and his co-workers (Priestley and Scott, 1936, 1937; Priestley, Scott, and Gillett, 1935; Scott and Priestley, 1925; Smith, 1941) are considering vascular development with reference to the phyllotaxy of the plant. These various methods of approach to the study of vascular initiation will have to be coordinated before a complete and unified picture of vascularization of shoots can emerge. The present study is an attempt at such a coordination. In particular it is concerned with the comparative patterns of initial development of the

procambium, the xylem, and the phloem, and with the relation of the course of vascularization to the phyllotactic pattern of the plant.

MATERIAL AND METHODS.—*Linum perenne* was chosen for this study because of its relatively simple vascular system. This species has only one trace per leaf and very few axillary buds. The simple structure of the plant proved particularly advantageous in the determination of the longitudinal course of development of the first vascular elements—the subject to be considered in the second article of the series. For the study of procambial differentiation, however, more suitable material than flax could have been chosen. Generally, plants with opposite leaves are most convenient for studies of the histogenesis at shoot apices because of the relative ease with which the shoots of such plants can be oriented on the microtome to give median sections of the youngest primordia. The flax has alternate leaves which are considerably crowded. The cells of the *Linum perenne* shoot apices are relatively small, another disadvantage in the study of histogenetic details.

The shoots were collected at different times during the spring and summer from several plants growing outdoors. The slides were prepared by the ordinary paraffin method, with normal butyl alcohol as a paraffin solvent and a paraffin-beeswax-rubber mixture as embedding medium. Chrom-acetic-formalin and

¹ Received for publication June 18, 1942.

formalin-acetic-alcohol mixtures were employed for killing and fixing. All the photomicrographs were taken from material treated with the chrom-acetic-formalin solution. The sections which were cut 6 to 7 microns thick were stained with a combination of iron-alum-hematoxylin and safranin according to a schedule previously indicated by the writer (Esau, 1941). The principal feature of this schedule is that the hematoxylin is used in a very dilute solution and is not allowed to overstain the sections. The method is very simple and gives good wall differentiation.

THE GENERAL CHARACTERISTICS OF THE PROCAMBIUM.—The small leaves are arranged according to variable phyllotactic patterns on the slender stem of *Linum perenne*. The phyllotaxy and the organization of the vascular system of this plant will be considered in the second paper. Here it will suffice to indicate that each leaf has a single trace and that the different traces anastomose within the stem in a characteristic manner, so as to form a network. In transverse sections the network appears resolved into discrete units—the vascular bundles (fig. 12).

As is well known, the precursor of the primary vascular system is a meristem which is commonly referred to as *procambium*.² The procambium of the flax stem, like that of other plants, forms a network similar to that of the mature vascular system. Since, however, the procambial network is delimited before the internodes elongate, all its parts are very short. Largely through elongation of cells the procambial strands keep pace with the elongation of the internodes.

A superficial examination of shoot-apex sections indicates that the procambium occurs very close to the apical meristem (fig. 1). It also shows that the typical narrow elongated shape of the procambial cells is acquired gradually, the cells nearest the apex being the shortest (fig. 1-3). The density of the cytoplasm of the young procambium cells is a very striking feature (fig. 1-4, 11, and 22), and in stained sections the procambium strands frequently appear darker than the youngest cells at the apex of the shoot (fig. 1; compare also figures 4 and 5). Perhaps the procambial cells have actually somewhat denser protoplasts than the cells at the apex, but two other circumstances are, no doubt, largely responsible for the characteristic appearance of the young procambial strands. Firstly, they are flanked by the considerably vacuolated parenchyma cells of the pith and cortex, and the light staining of these cells emphasizes the darkness of the procambium. Secondly, the procambial cells have small transverse diameters; they are even smaller than those of the cells at the very apex (compare procambial cells indicated by arrows in figures 5 and 10 with the apical-meristem cells in figures 5 and 6, respectively), so that in a given depth of a longitudinal section more cells occur in the procambium than in the adjacent parenchyma. Still another feature of the procambium often con-

tributes to its dense appearance: in sections fixed less satisfactorily than usual, procambial protoplasts are considerably more shrunken than those of the parenchyma about them.

Incidentally, the procambium is not the only tissue that appears denser than the apical meristem. The leaf primordia which are, essentially, areas of active cell multiplication, stain very deeply (fig. 1-5, and 8). Furthermore, dense staining is evident in the peripheral part of the axis just below the apex (fig. 1 and 5), the part where the divisions occur that are concerned with the lateral expansion of the axis and the initiation of leaf primordia.

In older regions of the stem the procambial cells undergo a pronounced vacuolation (see the central parts of the bundles in figure 29) until the procambium becomes as highly vacuolated as the cambium.

THE DELIMITATION OF THE VASCULAR REGION IN THE SHOOT APEX.—The literature pertaining to the phenomena of the first delimitation of the vascular region in shoot apices is being reviewed in detail in a special article (Esau, 1943). Only the most important of these works are considered here again and only very briefly. According to Louis (1935), the vacuolation³ and enlargement of the cortical and pith cells bring about a delimitation of the meristem *prodesmogen* within which the vascular system is eventually differentiated. Helm (1931) suggested the term *primary meristem ring* for the thus delimited precursor of the vascular system of the axis, because in transverse sections of the latter the meristem appears as a ring. Kaplan (1937) emphasized the variability in shape of this meristematic region in different types of plants and organs and proposed the term *residual meristem* for it, as well as for all other regions which remain in a meristematic state below the apex, after certain other tissues of the same level have ceased to function as meristems. The term *residual meristem* implies that the meristem is a remainder of the apical meristem. Helm (1931) and Louis (1935) agree with Kaplan that, when first delimited, the precursor of the vascular system is a remnant of the apical meristem; in fact, all three workers stress the similarity of this meristem with the apical meristem. It is delimited because the adjacent tissues become modified and not because it itself changes. This meristem is not yet procambium: the remainder of the apical meristem undergoes certain characteristic changes before it becomes procambium.

Louis (1935) points out that the blocking out of the prodesmogen does not occur above the youngest leaf primordia. On the contrary, the delimitation of the vascular system of the axis occurs in an intimate relation with the differentiation of the leaves. The base of the leaf, the so-called "foliar buttress," constitutes a part of the axis. Hence, when the prodes-

² The writer prefers *procambium* to the recently introduced *provascular tissue* or *provascular meristem*. The reasons for this preference will be considered in a forthcoming review article (Esau, 1943).

³ Since all cells, including those of the apical meristem, are more or less vacuolated (Zirkle, 1932; Foster, 1942), statements in this paper, to the effect that one tissue vacuolates and some other does not, mean that at a given stage of development of the axis one tissue is more conspicuously vacuolated than another. For convenience of expression the comparative form is seldom used.

Fig. 1-5. Longitudinal sections of shoot apices.—Fig. 1 and 5. Median sections of shoot apices showing the apical meristem and leaves in different stages of development. The white lines at *a* to *h* indicate the approximate levels of figures 6 to 12 and 26, respectively. $\times 120$ and $\times 500$.—Fig. 2 and 3. Two successive sections 7 microns apart, showing the trace procambium of a young primordium. $\times 280$.—Fig. 4. A similar section as in figure 3 but of a younger primordium. $\times 500$.

mogen becomes delimited in the leaf primordium and its buttress, it is also blocked out in the axis. In the large-leaved dicotyledons the parenchymatous differentiation of the cortex and pith occur approximately at the same level, so that the prodesmogen

early assumes a ring-like form in transverse sections of the stem. The medullation of the axis of gymnosperms and small-leaved angiosperms typically begins higher than the parenchymatization of the cortex (Louis, 1935; Kaplan, 1937), and, consequently,

the future vascular region is at first not set off from the cortex, the two together appearing as a "peripheral meristem" (Kaplan, 1937).

Linum perenne is an example of a small-leaved dicotyledon in which the vacuolation of the pith is evident at a higher level than that of the cortex (fig. 1, 5, and 6-12). Comparatively uniform and fairly dense cells occur through about the first 30 microns of the apex (fig. 6; 1 and 5 at *a*). Farther below, the vacuolation of the pith cells sets in, but the peripheral region, where the cortex and vascular tissues will differentiate, remains densely cytoplasmic (fig. 7; 1 and 5 at *b*). The leaf primordia are initiated at this level (fig. 7, 13, and 15). The contrast between the lightly-staining vacuolated pith and the peripheral-meristem region is very striking about 50 microns below the apex, where the pith cells show also considerable enlargement (fig. 8; 1 and 5 at *c*). The differentiation of the pith progresses very rapidly. A short rib meristem (fig. 1 at *d*; 5 between *b* and *d*) is succeeded by the young pith in which intercellular spaces appear (fig. 1, 5, 9, and 10). Still farther below, the pith disintegrates (fig. 1, 11, and 12). The level at which the pith breaks down varies somewhat in shoots collected during different times of the season, the examples shown here representing types with rapidly disintegrating pith.

Louis (1935) would say that the prodesmogen constitutes the inner portion of the peripheral meristem at levels shown in figures 8 and 9. Eventually the parenchymatization of the cortex would occur and delimit the prodesmogen on the outer side. The early stage of cortical vacuolation in flax is slightly indicated in figure 10. In the axils of some of the primordia evident in this figure the protoplasm of the parenchyma appears somewhat lighter than that of the primordium itself and of the subjacent layer of tissue (fig. 10, white arrows). In the words of Louis (1935), the ventral parenchymatization of the foliar buttresses has set in. In figure 11 the parenchymatous differentiation has involved also the dorsal sides of the buttresses, and the cortex is, therefore, defined around the entire axis. The vascular region is now clearly delimited. It is, at this stage of development, not a homogeneous meristematic cylinder but is composed of discrete procambial strands alternating with the comparatively highly vacuolated interfascicular areas. Thus the vascular system, when first completely delimited by the vacuolation of the pith and the cortex, is past the stage of prodesmogen in Louis' (1935) sense. Neither is there any evidence at higher levels of a region that could be interpreted as prodesmogen (Louis, 1935) or primary meristem ring (Helm, 1931). A careful comparison of transverse and longitudinal sections shows that processes initiating procambium may be followed to the highest levels of the axis at which leaf primordia are being formed. Before the vascular system is finally delimited, procambial differentiation is indicated by active longitudinal divisions in localized areas of the inner part of the peripheral meristem (fig. 10 and 21). Divisions occur throughout the peripheral meri-

stem, but are obviously more numerous in these areas. Strands of narrow cells, the procambial strands, result from the localized divisions (fig. 11 and 22). At the upper levels of the axis (fig. 8 and 9) the youngest procambial cells are not obvious. The rows of these cells converge toward the apex and, therefore, in transverse sections, the procambial strands are cut on a bias and the relatively small diameters of their cells are obscured. On the other hand, at the highest levels of procambial differentiation, the cytoplasm of the procambium is not yet strikingly different in its density from that of the other cells in the peripheral region. Longitudinal sections, however, indicate that divisions leading to procambial differentiation occur at these levels (fig. 13 and 15).

Thus the procambial divisions are evident in connection with the youngest leaf primordia, that is, directly below the apical meristem (fig. 13 and 15), and no meristem is interpolated between the apex and the procambium that would merit a special designation as prodesmogen or meristem ring. The vascular region begins its existence at the apex not as a homogeneous meristem, not as a remainder of the apical meristem, but as a region in which certain groups of cells are in the process of being differentiated as procambial cells.

THE LONGITUDINAL COURSE OF DEVELOPMENT OF THE PROCAMBIUM.—According to Louis (1935), the prodesmogen of the leaf and axis is blocked out as a unit. Furthermore, the prodesmogens of the successive leaf buttresses are confluent, so that the vascular system of the axis is from its inception a continuous structure. Although Louis (1935) did not consider the phenomenon of procambization, his paper indicates that he regarded the delimitation of the prodesmogen and the differentiation of the procambium as two distinct phenomena (see review by Esau, 1943). The initial unity of the prodesmogen did not, therefore, imply unity of the procambium. Many workers hold the view that the procambium first appears at the base of the leaf and thence differentiates acropetally into the elongating leaf and basipetally into the axis (see review by Esau, 1943). Recently, however, students of apical meristems have begun to bring forth evidence that the procambium differentiates acropetally in complete continuity from the axis into the leaves (Boke, 1940, 1941; Satina and Blakeslee, 1941); or that at least it is continuous at all times in a given internode and leaf (Cross and Johnson, 1941; Cross, 1942).

The study of the course of procambial development is difficult because of several structural features. Firstly, the transition from the embryonic cells characteristic of the apex to the narrow elongated cells of the procambium is very gradual and one must decide somewhat arbitrarily what cells should be interpreted as the first procambial cells. Secondly, the procambium is apparent in connection with the youngest leaf primordia in the portion of the axis where the internodes, and with them the parts of the procambial system, are still extremely

Fig. 6-12. Transverse sections of a shoot taken, respectively, the following number of microns below the apex: 12, 36, 54, 72, 90, 132, 294. The approximate positions of these sections are indicated in the longitudinal sections in figures 1 and 5 at *a* to *g*, respectively. The rectangles in figures 10 to 12 indicate the areas which appear more highly magnified in figures 21, 22, and 24, respectively. Fig. 6-10, $\times 250$. Fig. 11 and 12, $\times 160$.

Fig. 13-20.—Fig. 13-15. Longitudinal sections of shoot apices illustrating early stages in the organization of the trace procambium. Nuclei have been drawn in the cells concerned with the formation of new leaf primordia and of the procambium. Figures 13 and 14 represent two sections 14 microns apart from the same apex; the former shows the upper, the latter the lower part of the trace of the youngest primordium. The use of two sections was necessary because in figure 13 the trace terminated above the gap of a lower leaf. For proper orientation regarding levels one leaf has been marked with an *a* in both views.—Fig. 16-20. Transverse sections of stem showing differentiation of trace procambium. Nuclei have been drawn in procambial cells only; *st*, sieve tube; *x*, xylem element. The sections were taken the following number of microns below the apex, respectively: 98, 140, 245, 315, 385. The leaves whose traces appear in figures 16, 17, and 18 were 21, 70, and 266 microns high, respectively; in figures 19 and 20, over 400 microns high. All figures $\times 397$.

short, so that the course of the individual bundles is not readily followed. Thirdly, the procambial strand of a given leaf differentiates in an oblique manner above the gap associated with the attachment of the next lower leaf located on the same vertical line as the first leaf. (Gaps are indicated with arrows in fig. 1 and 12.) If the procambium is followed in successive transverse sections, the identity of this meristem is easily lost where the strand, because of its oblique

course, is cut on a slant. A clear understanding of the phyllotaxy and interconnection of traces of the given plant helps to reduce this difficulty. The continuity of procambium in the gap region is more readily established in longitudinal than in transverse sections. A median longitudinal section through a leaf primordium would, of course, show an apparent break in the continuity in the procambium strand directly above the gap parenchyma (fig. 2). But a section which is

Fig. 21-29. Transverse sections of stem and leaves showing differentiation of procambium and of first vascular elements; *st*, sieve tube; *x*, xylem or xylem element. The stem sections in figures 21, 22, 24, 26, and 29 were taken the following number of microns below the apex, respectively: 90, 132, 306, 582, and 1,062. The sections in figures 23, 25, 27, and 28 were taken from leaves that were removed the following number of plastochrones from the apex, respectively: 36, 44, 45, 51. All figures $\times 750$.

off median (fig. 3), particularly if it is somewhat slanting, will reveal the continuity of the strand across the gap region.

In the present study the differentiation of the pro-

cambium in the flax axis has been followed in transverse and longitudinal sections from its inception to the early stages of phloem and xylem differentiation (fig. 21-29).

Using the tunica-corpus concept of the structure of apical meristems, the *Linum* apex is here classified as one having a single tunica layer overlying a corpus of about three layers of cells (fig. 5). Sometimes it appears as though there are two layers of tunica but periclinal divisions contributing cells toward the corpus are common in the second layer from the surface (fig. 5 at left above). The leaf primordia are initiated by periclinal and other divisions in the corpus (fig. 4, 13, and 15). Longitudinal divisions in the inner layer or layers of the corpus result in the formation of slightly elongated cells (fig. 13 and 15). These cells are the uppermost members of a strand of similar cells that may be followed downward into the axis to the level where these cells definitely assume the characteristics of the procambium (fig. 13 and 14, which show the same strand at two levels; fig. 4) and are connected with the procambium of other leaf traces. In the inner layers of the corpus periclinal divisions may be detected before such divisions in the outer corpus layer indicate the initiation of a leaf primordium. Figure 5, for example, shows at the left the repeated doubling up of the second corpus layer while the tunica and the first corpus layers remain single. The deep periclinal divisions in the flanks of the apical cone are concerned, however, not only with the formation of the procambium but also with the augmentation of the number of cortical layers. In similar manner, periclinal divisions in the outer corpus layer (second layer from the surface) are not restricted to the areas where leaves are initiated but occur also beneath the primordia (fig. 4 and 15). All these periclinal divisions occur in such close sequence that the products of the divisions tend to become aligned in oblique radial rows (note the cell rows indicated by arrows in fig. 4) in which it is difficult to distinguish between the future cortical and the future procambial cells until the degree of vacuolation in the two kinds of cells becomes conspicuously different (fig. 4), and the procambial cells assume their elongated narrow shape.

A summing up of the data on the longitudinal course of procambial differentiation in the flax apex gives the following sequence in the process. Periclinal and other longitudinal divisions proceed acropetally in the meristematic flanks of the axis tip as the latter becomes elevated through the activity of the apical meristem. Where leaf primordia do not arise, the subsurface products of the divisions become the cortical cells. Within the inner layers of the peripheral meristem divisions become particularly prominent beneath the areas where divisions in the outer corpus layer initiate the leaf primordia. These localized divisions, periclinal and others, form the procambial strands. The new procambial strands are continuous with the procambium of the older leaf traces. Thus the procambium of the shoot apex differentiates in a continuous acropetalous manner.

THE DIFFERENTIATION OF A PROCAMBIUM STRAND AS SEEN IN TRANSVERSE SECTIONS OF STEM AND LEAF.—As was already emphasized, a sharp demarcation between the procambium and the adjacent cells is

lacking in the early developmental stages of this meristem. Transverse sections clearly show that for a certain time the procambium strands increase in diameter not only by cell division within them but also by the addition of cells on their periphery from the surrounding tissue.

In figure 10 the two black arrows are pointing at small groups of cells that have resulted from recent divisions and by their position and density of protoplasts indicate that they are procambial cells. Figure 5 at level *e* (cells indicated by arrows) shows that similar recently divided cells in this region are elongated like young procambial cells. In figure 16 a procambial strand in earliest stages of development has been illustrated. (The procambial cells in this figure and also in figures 17 to 20 are marked with circles which represent nuclei.) The figure shows that some divisions have occurred—one is still in progress—around the small procambial strand. Some of the walls have been laid down parallel to the circumference of the strand, others in other planes. By these divisions cells are added to the periphery of the strand while divisions also continue within the strand itself. Since the divisions within the strand occur before the cells enlarge to the size of the mother cells from which they arose, the resulting procambial cells become conspicuously smaller in transverse section than the adjacent parenchyma cells. Figures 17 and 22 show procambial strands just before the beginning of phloem differentiation. To the right and left of these strands cells are dividing. New strands—the traces of higher leaves—will result from some of these divisions. A given transsection, therefore, contains procambial strands of different degree of differentiation depending on the age of the leaf with which they are connected.

While the divisions within the procambial strand continue and additional cells still become incorporated into them on their flanks the first vascular elements begin to differentiate. As is typical of the angiospermous shoots (see reviews by Esau, 1939, 1943), the first vascular cell to mature in a leaf trace is a photophloem sieve-tube element. The characteristic appearance and the sequence of developmental changes of the first sieve tubes in stems, roots, and leaves have been previously described by the writer (Esau, 1936, 1938, 1939, 1940). Therefore, the structure of these elements in flax is characterized only very briefly. The first sieve tubes may readily be distinguished in transverse sections by their somewhat thick primary walls which stain deeply with hematoxylin (fig. 24–29). The mature sieve-tube elements lack nuclei and their cytoplasm is scarce and stains very lightly, so that the cells appear as though they were free of contents. Immature protophloem sieve tubes have dense protoplasts (fig. 23; fig. 28, element at right arrow; fig. 29, elements lying to the extreme right and left in the group marked with arrows in the large bundle). The characteristic wall thickening appears before the nucleus disintegrates and the cytoplasm becomes thin (fig. 23, 28, and 29). These protophloem elements merit the des-

ignation as sieve-tube elements because they possess sieve plates.

The development of the procambium strands within the midvein of the leaf and within the trace follow a similar course as indicated by a comparison of figures 23, 25, 27, and 28, taken from leaves, with figures 17 to 20, 24, and 26, taken from stem sections.

Figures 18 and 23 show the appearance of a procambium strand during the late developmental stages of the first sieve-tube element. While this element matures (fig. 19 and 24) the procambial cells continue to divide longitudinally, particularly at the xylem pole. Most of these late procambial divisions occur in periclinal planes so that the new cells at the xylem end of the bundle become oriented in radial rows (fig. 19). Before many of these periclinal walls are produced a cell on the inner periphery of the procambial strand shows a conspicuous thickening and deep staining of the primary walls similar to those of the differentiating sieve tubes (cells marked *x* in fig. 20, 25, 26, and 29). These cells are the first xylem elements. In their subsequent stages of development the xylem elements develop lignified spiral secondary thickenings (fig. 27). In fully mature state they lack protoplasts (fig. 28; and 29, the two xylem cells indicated by the shortest arrow in the large bundle). The elements commonly have more or less oblique ends which overlap where two superposed elements are connected with each other. Whether the end walls are perforated has not been determined.

The tendency toward tangential orientation of the new walls produced by the later divisions of the cells which occur between the xylem and phloem poles becomes more pronounced with further bundle development. Moreover, the dividing cells become increasingly vacuolate (fig. 25-29). Eventually these cells are conspicuously set off from the densely cytoplasmic phloem and xylem regions as radially seriated vacuolated cells (fig. 29). Thus the procambium assumes certain characteristics of the cambium: high degree of vacuolation, predominance of tangential longitudinal divisions, and the resulting orderly radial seriation of the immediate products of division. The cells in the interfascicular areas keep pace with the radial increase in the size of the differentiating vascular bundles by occasional periclinal divisions (fig. 29). When at the end of primary growth of the axis the fascicular cambium becomes organized within the bundles, cambium appears also in the interfascicular areas, the periclinal divisions thereby becoming localized in a narrow zone, which is continuous with the fascicular cambial zone. As is typical of

seed plants (see Esau, 1938, p. 356-361; 1943), the transition from the primary to the secondary growth is gradual as seen in transverse sections of flax shoots.

SUMMARY

The procambium in the vegetative apices of *Linum perenne* L. is initiated in the form of strands, as a result of repeated longitudinal divisions within the peripheral meristematic region which becomes delimited as such because of the early differentiation of the pith.

The divisions initiating the procambium are localized beneath the areas where leaf primordia emerge and are evident during the earliest stages of leaf formation, at the time when the primordium does not yet form a bulge on the surface of the apical cone.

The leaf and its procambium are initiated immediately beneath the apical meristem. No distinct meristematic region is interpolated between the apical meristem and the procambium that would merit the designation of "meristem ring" or "prodesmogen" in the sense of Helm (1931) and Louis (1935), respectively.

The procambium strands differentiate in continuity with the procambium of the older traces within the axis and progress acropetally from the axis into the developing leaves. Thus the present study supports the emerging concept (Esau, 1943) that the procambium may differentiate within the axis as a continuous system, and not like the first xylem which appears as isolated segments that subsequently become connected.

In their early stages of differentiation the procambium strands are not clearly separated from the adjacent cells of the peripheral meristematic region. The morphologic differences between the procambium and the adjacent parenchyma develop gradually; furthermore for a time the procambium strands increase in size by the addition of cells on the periphery—cells resulting from divisions of adjacent nonprocambial cells.

Divisions occur also within the procambial strand and continue after the differentiation of the first vascular elements. In the procambium of a leaf trace a sieve-tube element is the first conducting cell to mature. Then the first xylem element matures. When the xylem begins to differentiate, the procambial divisions tend to become oriented tangentially.

THE SIGNIFICANCE OF OXIDATION IN THE ENDODERMIS¹

D. S. Van Fleet

AS REPORTED earlier (Van Fleet, 1942) there is an oxidase system associated with the development of the endodermis in monocotyledonous and dicotyledonous plants. It is the belief of the author that this oxidase system is an active oxidation center responsible for the characteristic appearance and irregularity in the distribution of the endodermis in stem, root and leaf. In order better to understand the function and development of this tissue, experiments and observations were conducted which give a more exact picture of the nature of the oxidative processes and reveal some new facts about oxidation-reduction in the endodermis. A critical analysis of these facts makes quite clear the normal and characteristic interactions taking place between the endodermis and tissues of the stele and cortex.

Ecological and general habitat factors influencing the endodermis have been recognized by Schwendener (1883), Müller (1906), Haberlandt (1914), Van Fleet (1942) and others. Priestley and his students have demonstrated both internal and external environmental conditions believed to be connected with the functional development of the endodermis. It is hoped that the work reported here will help to clarify the relationship between external and internal factors recognized by earlier workers and will at the same time serve as a basis in method and approach to further work on this and other tissues which differentiate and function in terms of environmental factors.

METHODS OF STUDYING THE OXIDASE SYSTEM.—Freehand or sliding microtome sections of living roots and stems were made and immediately immersed in oxidase indicators. In a few cases the injection method was used to substantiate or verify the results of the application of indicators to fresh sec-

tions. The following indicators were used: guaiacol, para-phenylenediamine-hydrochloride + alpha naphthol, diphenylamine, benzidine, diphenylbenzidine, potassium-iodide-starch, titanium sulphate, etc. The indicator best suited for the endodermal oxidase system is guaiacol, because it does not oxidize in the absence of oxidase under alkaline conditions as do most of the above named indicators.

In order to modify the behavior of the oxidase system, plants were grown in various nutrient solutions that contained either pro-oxidants, antioxidants or inactive substances such as salts or organic substances. Much of the study of pro- and antioxidants was conducted on roots of *Allium* grown in solutions and in washed sand according to methods outlined in an earlier paper (Van Fleet, 1942). Solutions of pro-oxidants and antioxidants were also applied to fresh sections immediately before placing them in the indicators.

In addition to noting the behavior of the oxidase system, the distribution of the endodermis and the centripetal development and deposition of various substances were carefully observed in terms of the nutrient solutions used and in connection with oxidation-reduction processes taking place in the endodermis.

MECHANISM OF OXIDATION-REDUCTION SYSTEM IN THE ENDODERMIS.—By using various indicators, such as the Sudan stains, rosaniline, Scarlet R, iodine, potassium iodide or hydriodic acid, it is possible to demonstrate the presence of unsaturated fats and fatty acids in the plasma membrane and primary wall of the endodermal cell. These unsaturated substances of a suberogenic nature are deposited in the primary wall of the endodermis where they form peroxides at the unsaturated bond. Guaiacol, "Nadi" reagent, "Dopa" and other indicators are oxidized

¹ Received for publication June 20, 1942.

in the direct reaction, without introducing hydrogen peroxide, demonstrating that the peroxide is formed by an oxygenase system and further decomposed by peroxidases. The accumulation of decomposition products as a result of peroxide formation and decomposition may be demonstrated by applying orcinol, resorcinol, phloroglucinol and other similar indicators commonly used to demonstrate the presence of aldehydes. Other degradational products such as tannins and phlobaphenes accumulate at the same time that the aldehydes are formed. Extracts of tan-

Fig. 1-2.—Fig. 1. Diagram to show oxidative action in the endodermis opposite the xylem and the phloem in a root. Oxidation, as indicated by stippling, is most intense in “gap cells” and in the outer tangential walls of the endodermis opposite the phloem.—Fig. 2. Diagram of a mature endodermal cell in which the most intensive oxidase activity is in the outer tangential wall. The oxidase action associated with the Casparian strip, a juvenile feature of the cell, is also indicated.

nins, from strips of tissue containing the endodermis, are easily precipitated by ferric chloride, iron alum, potassium ferrocyanide, etc., and these reagents give the characteristic color reactions indicating that tannins are present, and the application of dilute sulfuric acid frequently shows the bright red and characteristic color of phlobaphenes and other oxidation products derived from tannins. The common occurrence of phlobaphenes may be demonstrated by deep red-brown color in the presence of potassium hydroxide, by red color in acid, and by their easy solubility in methyl, ethyl, and propyl alcohol.

The unsaturated fats of the endodermis convert molecular to atomic or peroxide oxygen which brings about the oxidative decomposition of the fats and other accompanying substances, such as carbohydrates, tannins, etc., or indicators applied to the living system. This autoxidation of the unsaturated hydrocarbons in the endodermis may be made evident by the liberation of iodine from potassium iodide or dilute hydriodic acid with soluble starch as an indicator. The iodine liberated by oxidation of the unsaturated fats is immediately absorbed by the oxidizing system so that the plasma membrane and the walls of the endodermis become brown. The oxidation of various indicators (guaiacol, Nadi and Dopa) and the ability to absorb, point to the importance of the unsaturated substances of the endodermis as centers for the oxidation.

Priestly (1924) has proposed that unsaturated substances are oxidized as are the “drying oils” to become deposited as suberogenic materials. It has been demonstrated further that oxidation in the endodermis is like that of an oxidase system (Van Fleet, 1942); and, as has been pointed out here, the nature of the oxidase system is that of an unsaturated fat undergoing peroxide formation and decomposition. It is quite apparent that the unsaturated bonds converted to peroxide linkages become the energy source for further desaturation and peroxide promotion. The dehydrogenation of the fatty acid may be brought about by the formation and decomposition of the peroxides.

The question may arise as to whether the oxidase system of the endodermis may be called an oxidation system. Can it be demonstrated to be an oxidase system and at the same time be recognized as an active center for oxidation? The oxidation of the common indicators for oxidases is the basis for assuming the presence of an oxidase system. The autoxidation of any substance in such a way as to prevent the destruction of the system and at the same time to oxidize other foreign components or introduced indicators may be thought of as a type of oxidase system. According to Gallagher (1923) substances similar to

TABLE 1. Action of pro-oxidants on the oxidase system of the endodermis

Pro-oxidant	Concentr.	pH	Intensity of reaction	
			Endodermis	Other tissues
	%			
Cupric chloride	1	6-7	++++	++
Cupric sulphate	1	6-7	++++	++
Barium hydroxide	1-7	8-9	++	+

Sodium selenite25	7.5	++	+
Sodium selenite12	7	+	++
Thiourea	1	6-7	++	+

lipins will bring about the oxidation of guaiacum in the presence of peroxidase. In the literature of industrial oils and fats there are many instances of spontaneous decomposition of unsaturated substances which behave as "oxidase systems," in that they oxidize the usual indicators, and at the same time actively oxidize the members of the system and other accompanying substances that may be present. Tauber (1940) and Strain (1941) report an unsaturated fat oxidase, present in legumes, which brings about peroxide formation in fats and as a result carotenoids present are oxidized.

PRO-OXIDANTS AND ANTIOXIDANTS.—The evidence obtained from a study of pro-oxidants and antioxidants substantiates the viewpoint that unsaturated fats are responsible for the oxidase reaction and that any substances inhibiting this reaction tend also to check the oxidation of fats and deposition of resultant degradational products in the endodermis. Those substances acting to accelerate oxidation through peroxidation are listed in table 1 as pro-oxidants. The action of pro-oxidants on the oxidase system of the endodermis is best studied by applying dilute solutions of the pro-oxidant to fresh living sections of stem or root followed by the application of some indicator such as Nadi reagent, guaiacol, diphenylbenzidine, etc. The plants best adapted for this study are young stems of *Asparagus*, *Smilax*, *Tradescantia* and *Vicia faba* and for root studies *Allium sativum*, and other species of onion or roots of peas, beans, or corn. The results of many trials of dilute solutions of inorganic and organic reagents are given in tables 1 and 2. The concentration and pH of the pro-oxidants

TABLE 2. Reagents acting as antioxidants

Acetone	Potassium sodium tartrate
Acetic acid	Potassium thiocyanate
Ammonium oxalate	Pyrocatechol
Ammonium sulphocyanide	Pyrogallol
Barium chloride	Pyroligneous acid
Carbonic acid	Sodium acetate
Chloral hydrate	Sodium ammonium phosphate
Cobalt chloride	Sodium benzoate
o-Cresol	Sodium chloride
Ferric chloride	Sodium citrate
Hydriodic acid	Sodium cyanide
Hydrogen sulfide	Sodium hyposulphite
Hydroquinone	Sodium nitrate
Iodine	Sodium nitrite
Potassium chloride	Sodium salicylate
Potassium ferricyanide	Sodium sulfate
Potassium ferrocyanide	Sodium sulfite
Potassium hydroxide	Sodium thiosulfate
Potassium iodide	o-Toluidine

are listed in each case along with the intensity of reaction that immediately followed their application. The intensity of peroxidation is recorded by taking the plus sign (+) as the reaction of the tissue without the application of either pro- or antioxidants.

It has long been recognized that the oxidation of an unsaturated fat is greatly increased under alkaline conditions, and the alkaline oxidation by hydro-

gen peroxide of a fatty acid, in the Dakin reaction, is a familiar one. The alkaline salts (table 1) function as pro-oxidants because they make the unsaturated fats more alkaline and bring about alkaline oxidation. The condensation of unsaturated substances and the accompanying oxidation are inhibited under acid conditions. Under stronger concentrations of alkaline salts the saponification of fats in the endodermal plasma and wall may be observed, and there is a partial saponification of fats taking place when the alkaline salts are present in dilute form. This partial saponification catalyzes peroxidation since free fatty acids are apparently conducive to the inception of oxidation. It is also possible that oxidation may accelerate saponification, at least this has been found to be true *in vitro* according to Stebnitz and Sommer (1937). The increased oxidase activity under alkaline conditions brings about a greater oxidation and deposition of unsaturated substances (Van Fleet, 1942), and the increase in oxidation under alkaline conditions is in keeping with the observations of Rose (1915) and Rose, Kraybill and Rose (1920).

It has been pointed out by Priestley (1924), and Lee and Priestley (1924), that fatty substances are saponified and migrate to surfaces as soaps and become deposited by evaporation and are then oxidized and undergo condensation. Further information in support of Priestley's belief has come from the work with pro-oxidants. The most effective pro-oxidants (table 1) are those that are capable of aiding in the saponification of fats in the endodermis (sodium selenite, sodium borate, etc.). This fact leads one to conclude that saponification in the plant may be accompanied by oxidation. Observations reveal that oxidation and saponification occur simultaneously at some surface where molecular oxygen is present. The endodermis as a bounding tissue at the inner edge of an aerating tissue, the cortex, becomes the locus for saponification and oxidation. The release of active oxygen that accompanies these reactions would of course catalyze saponification and at the same time it would bring about immediate deposition through condensation of the constituents of the system.

Sodium selenite (table 1) increases oxidase activity in the endodermis, but it decreases oxidase action in other tissues. Wright (1938) has demonstrated that selenite-poisoned mammalian tissues consume less oxygen and are not able to oxidize glucose but can oxidize p-phenylenediamine. With a decrease in concentration of selenite, oxidation in the endodermis diminishes and at the same time oxidase action in the cortex, hypodermis and epidermis is augmented. Sodium selenite augments oxidation in the endodermis at concentrations ranging from saturated solutions down to 1%, but below 1% the oxidation in the endodermis diminishes and in other tissues it increases. Under sodium selenite, oxidation in the endodermis is in direct proportion to the concentration, and at the same time oxidation in other tissues is in inverse ratio to the concentration of

selenite. Hence by using this reagent one may isolate histologically the oxidase system of the endodermis.

The alkaline salts decompose hydrogen peroxide compounds through their catalytic action and by their general alkaline condition which would render peroxides less stable. The alkaline pro-oxidants may conceivably be capable of increasing oxidation by decomposing peroxides and at the same time they saponify fats, which process is known to accelerate oxidative action. Saponification in the endodermal cell would lead to salt formation with resultant hydrolysis and ionization and the formation of alkali and free fatty acid. It is the belief of the author that salt formation and ionization accelerate oxidation.

Fresh alcoholic extracts or aqueous suspensions of chlorophyll act as pro-oxidants to the endodermal oxidase system and greatly increase the oxidation of indicators applied to the tissue after it has been covered with chlorophyll. Other surrounding tissues do not increase their oxidase activity. Chlorophyll acts as a catalyst both to saponification and oxidation through the action of the associated magnesium. Small amounts of magnesium chloride and copper chloride catalyze oxidation in the endodermis. Magnesium activates the oxidative decomposition of organic substances in the endodermis just as copper is already known to activate oxidation in commercial preparations of oils and gasoline.

It is not possible to reach any definite conclusion at present as to the part which copper plays in oxidation in the endodermis because copper will oxidize guaiacol (Moog, Garrigue, and Valdivié, 1939) and other indicators. Copper is apparently strongly adsorbed by the endodermal fatty system and acts as a part of the peroxidase reaction to release (O), and the Cu^{++} may be changed to Cu^+ by receiving electrons and hence oxidize indicators and other substances present.

Szent-Györgyi (1939) has pointed out that metal is alternately oxidized and reduced and thus becomes a catalyst through its change in valence. Under the influence of a catalytic metal, hydrogen atoms may be oxidized away from an organic substance to bring about dehydrogenation (autoxidation). Banga and Szent-Györgyi (1938) have demonstrated that Fe and Cu accelerate the autoxidation of dioximalcinic acid, and that here again electrons are passed in a chain reaction from metal atom to metal atom until finally the "electron acceptor," oxygen, is reached (Szent-Györgyi, 1939). Allott (1926) has shown that Fe increases the oxygen consumption of fats and fatty acids in the presence of glutathione. Smedley-Maclean and Pearce (1934) found that copper sulphate would bring about the *in vitro* oxidation of fatty acids in the presence of hydrogen peroxide. Ellis (1932, 1936) has studied the acceleration of autoxidation in fatty acids by catalysts. A peroxide is formed spontaneously according to Ellis, but it is possible to accelerate its formation by suitable catalysts (iron compounds), and Holtz (1936) has found that copper ascorbate and ferrous salts catalyze the *in vitro* oxidation of unsaturated fatty acids.

The organic antioxidants listed in table 2 inhibit oxidation in the endodermis just as they are also known to inhibit the autoxidation of fats (Olcott and Mattill, 1936). It is probable that they prevent the formation of peroxides in unsaturated substances associated with the endodermis. The inorganic antioxidants in table 2 are salts which are acid in aqueous solution and in this way they depress oxidase activity in the endodermis. Many of the organic and inorganic antioxidants have reducing properties, as for example, sodium sulfite, hydroquinone and pyrocatechol. Those which increase the acidity are ferric chloride, pyroligneous acid, sodium salicylate, etc. The following substances listed in table 2 have long been recognized as food preservatives and antioxidants: sulfur dioxide, sodium salicylate, boric acid, and benzoic acid.

Several dyes act as antioxidants in that they are absorbed by unsaturated substances which are then unable to undergo autoxidation. Rosaniline, Sudan III and IV, and Scarlet R act as excellent indicators for unsaturated fatty acids which are then prevented from acting as oxidase centers. This fact suggests that many of the antioxidants may act to prevent unsaturated bonds from forming peroxides and undergoing further oxidative decomposition.

The addition of tannic extracts from the bulb scales of *Allium* to nutrient media, in which roots were growing, greatly decreased suberization and condensation in the endodermis (Van Fleet, 1942). Tannins added to fresh sections prevented oxidation. It is probable that, as proposed by Moureau and Dufraisse (1922), the addition of tannins to autoxidizable compounds prevents the formation of peroxides. Tannins may then be thought of as antioxidants. The presence of antioxidants in aerial stems is the probable cause for the failure of the endodermis to put in an appearance, and it may well be that tannins produced during periods of active growth are responsible for inhibition of oxidation at the locus of the endodermis.

THE SIGNIFICANCE OF THE OXIDATION-REDUCTION SYSTEM.—Oxidation in the endodermis is initiated by the unsaturated fats and fatty acids characteristic of this tissue. Oxidation proceeds in the step-wise fashion associated with oxidase systems (diagram 1), and these oxidative reactions result in the molecular degradation of unsaturated and associated substances which are deposited in the endodermal wall. The importance of free molecular oxygen to this reaction has been demonstrated (Van Fleet, 1942). It is quite evident that the oxidation by peroxide or nascent oxygen must be preceded by two distinct steps, (1) the oxygenation of the oxygen acceptor, and (2) the action of peroxidase to split and release the peroxide oxygen from the acceptor. The accumulation and condensation of aldehydes, lignic and suberic substances follows the active period of autoxidation. The unsaturated fatty acids which are the centers for the oxidase system are oxidized to aldehydes and other decomposition products, and at the same time the energy thus released may result

Fig. 3-6.—Fig. 3. Photomicrograph of *Smilax rotundifolia* stem section, from the region of the ground line, to show a mature interrupted endodermis. Cells are dark because of an accumulation of oxidation and degradational substances. $\times 520$.—Fig. 4. Same as figure 3, showing location of endodermis on peripheral side of bundle. $\times 86$.—Fig. 5. Photomicrograph, by polarized light, of *Smilax* root, showing deposited oxidation products and "gap cell" at end of arrow. $\times 86$.—Fig. 6. Photomicrograph, by polarized light, showing isotropic zone of oxidation in the outer tangential wall of the endodermis and in the cortical layer outside the endodermis.

in the formation of unsaturated substances from the aldehydes. Release of (O) activates condensation reactions, and aldehydes, hydroxy-acids and fatty acids are polymerized. The addition of dilute

(0.0003%) quantities of hydrogen peroxide to sections and the resultant "browning" and condensation of tannins illustrates this point.

The mature endodermis is heavily supplied with oxidized aromatics and generic lignic materials in a basic matrix of cellulose. These polymerized products may accumulate to the point where they act as antioxidants and halt oxidation. The cells in figures 3, 4 and 5 gave only a weak oxidase test. In some *Smilax* roots there is a secondary zone of oxidation and deposition in the outer tangential wall of the endodermis and in the first cortical layer of cells outside the endodermis. This secondary oxidation zone is isotropic in polarized light as shown in figure 6. This oxidation zone develops after the first zone of oxidation in the endodermis has declined in oxidative deposition. As shown in figure 8 there is also an accumulation of condensation substances inside the endodermis in the stele.

The centripetal nature of deposition in the endodermis as it relates to the oxidation-reduction system.—The maturing endodermis is characteristically thickened to a much greater extent on the radial and inner tangential walls to give a centripetal type of deposition (fig. 3). The most intensive oxidase activity is, as shown in figure 2, in the immediate region of the outer tangential wall. The products of this oxidation accumulate in the inner part of the cell along with cellulose lamellae. In young endodermal cells opposite the phloem the oxidase activity is always most intense in the outer tangential portions, but in the endodermis opposite the xylem, oxidases

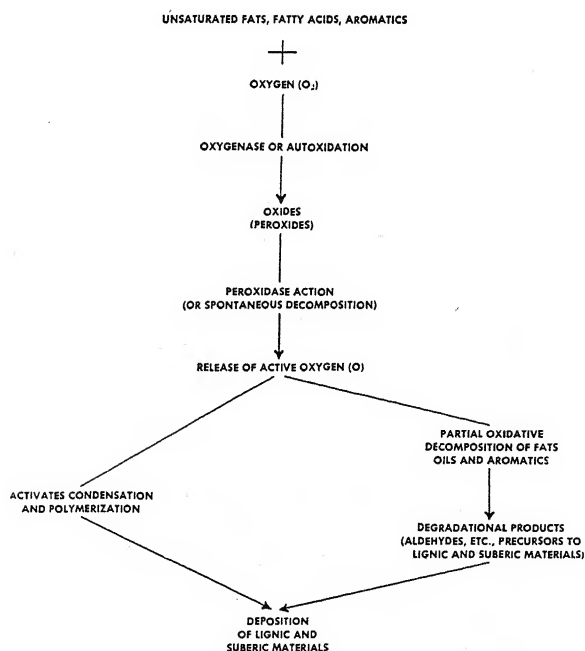

Diagram 1.—Significance and general trend of oxidation in the endodermis.

are distributed around the entire protoplast and around all walls. The more intense oxidase activity in the outer portion of the endodermis apparently prevents deposition in that part of the cell but brings about deposition in the inner portion by giving rise to the condensation substances. The appearance of the endodermis as a series of U-shaped cells is thus related to the intense oxidation in the outer tangential wall plus the concomitant condensation and polymerization that take place along the radial walls and the inner tangential wall. The lack of true cellulose in the outer peripheral part of the U-shaped endodermis is a result of the intense oxidation of unsaturated substances. The oxidation of unsaturated fats may bring about the oxidation and destruction of other substances, notably cellulose or cellulose precursors. The typical endodermal cell as seen in many monocotyledonous plants may be thought of as being composed of an outer or peripheral surface undergoing oxidation and dehydration while deeper portions of the cell and inner surfaces bring about the condensation of products resulting from oxidase activity.

The failure of inner portions of the young and maturing endodermal cell to oxidize indicators, tannins and chromogens present in the endodermis suggests that the inner region of deposition is either a zone of reduction or a "neutral" zone. One may then arrive at the logical conclusion that the greater prevalence of unsaturated fats in the outer tangential wall (Sudan stains, Scarlet R, chlorophyll, Rosaniline, etc.) is directly correlated with more intense oxidative action in this region, and it becomes evident that the endodermal cell (with the exception of "gap" cells opposite the xylem) is composed of an outer zone of higher oxidation potential and an inner zone which is at least low in oxidative properties if not a zone of reduction.

Fig. 7-8.—Fig. 7. Camera lucida drawing of mature endodermis in *Smilax rotundifolia* stem to show the occurrence of thin walls in the endodermis adjacent to thin-walled cortical or sclericycle cells. Arrow points to asymmetrical cell associated with thinly lamellated cells in both cortex and stele. $\times 520$.—Fig. 8. Diagram of *Smilax* stem to show accumulation of oxidized and polymerized substances in the endodermis and in the stele inside of the endodermis. $\times 70$.

In the inner or stelar side of the endodermis there is an accumulation of unsaturated materials and a concomitant but slight oxidation. There is a condensation of carbohydrates and fats to form cellulose

on the one hand and small amounts of suberic substances on the other. The failure of these materials to remain in an "active" condition is probably brought about by the influence of depositional factors in the underlying sclericycle and stelar elements. There is an accumulation of oxidized and polymerized substances in the lamellae of the endodermis nearest the stele (fig. 7) and also a slow deposition of similar material in underlying fibers during the growing season (fig. 8).

The unilateral deposition of cellulose lamellae to give the typical asymmetrical endodermal cell (fig. 3 and 7), so often seen in monocotyledons, points to an additional fact about the oxidation-reduction system. According to Hilditch (1940) it is possible for a carbohydrate system to be converted by reduction into a fatty system by an oxidation-reduction process in which hydrogen peroxide or atomic oxygen would be released and utilized by some substance, or oxygen acceptor, present in the system. The thin cellulose lamellae on the cortical side of the endodermis may be indicative of the conversion of carbohydrates to fats on this side of the endodermis. The abundant presence of unsaturated fats and peroxides on the cortical side of the endodermis, and the almost complete absence of cellulose in this zone would seem to be evidence of an oxidation-reduction conversion of carbohydrates such as Hilditch has suggested.

Relationship of endodermal oxidation to the xylem, phloem and cortex.—Fatty precursors to oxidase activity may originate in the phloem (Van Fleet, 1942), at least fatty oxidation and deposition first take place opposite the phloem. Unsaturated fats and oxidation may be noted later in the endodermis opposite the xylem. After oxidase activity opposite the xylem is initiated, it remains more intensive than opposite the phloem. Oxidase activity in cells opposite the xylem is not confined to the outer tangential wall as in the case of phloem but is found in and around all walls (fig. 1). The sustained oxidase activity in all parts of the endodermis opposite the xylem is the probable reason for the lack of centripetal deposition in these cells resulting in the typical "gap cell" so often associated with the xylem (fig. 1 and 5). Oxidative action is in general apparently stronger in the outer tangential wall and outer portions of the endodermis opposite the phloem than it is in any part of the endodermal cell opposite the xylem. This more intensive oxidation would of course lead to greater deposition and condensation opposite the phloem.

The greatest deposition in the endodermis of cellulose, lignic and suberic substances is away from the thin-walled cortical cells and is toward or next to the thick-walled and lignified sclericycle (fig. 3 and 7). This occurrence of the thinnest wall of the endodermis next to thin-walled cortical cells is strikingly shown in the asymmetrical cells one often encounters in *Smilax* stems. In figure 7 one of the endodermal cells has a dumb-bell-shaped lumen as a result of the concomitant occurrence of thin-walled parenchymal cells on both sides of the endodermis.

There are two thinly laminated areas in this asymmetrical cell, one opposite a cortical cell and the other nearest to a stelar cell, both of which are relatively thin-walled and are characterized by intense oxidative activity.

Oxidation is, as indicated earlier in this paper, more intense in the outer portion of the endodermis toward the periphery (fig. 6), and it is also true that oxidation is in general more pronounced in the cortex than it is in the stele or sclericycle. The thin-walled parenchymal cells infrequently found in the sclericycle (fig. 8) may also show more oxidative action. From the above observed facts, it would seem to follow that unilateral deposition is related to differences in intensity in oxidation and deposition. The endodermis as a differential between two widely different systems, the cortex and the stele, thus exhibits the characteristics of both systems, that is, the endodermis is more like the thin-walled cortical cells on one side and the thick-walled sclericycle cells on the other. Thus unilateral deposition of U-shaped cells is indicative of a differential between a zone of deposition and one of extremes in oxidation-reduction.

The cortical side of the endodermis is next to a fairly constant oxygen supply which would allow for immediate absorption of oxygen and, following this, peroxidation and resultant oxidation. The polymerization and condensation of oxidized products would necessarily follow at a slower rate and there is evidence, as reported earlier, that condensation and deposition of oxidation products proceed according to the amount of water in the cortex and the environmental medium.

The significance of the endodermis as a center for oxidation and as a differential between two extremely different tissue systems is closely linked with its function as a mature tissue. The mature endodermis with greatly thickened walls stops the outward diffusion of fatty substances from the stele. A plant with a functional endodermis shows only a slight oxidase activity in the cortex, and if the endodermis is interrupted or broken there are corresponding sections in the cortex where oxidation is much more pronounced (Van Fleet, 1942). The endodermis thus becomes a barrier to a part or all of the constituents of oxidase systems.

The distribution and differentiation of the endodermis as a result of oxidation processes.—The complete absence of the endodermis in aerial parts of most monocotyledonous plants (Müller, 1906, and Van Fleet, 1942) and the infrequent appearance of this tissue in above-ground parts of many dicotyledonous plants (Priestley and students) has led to much conjecture concerning the factors responsible for its appearance. According to Priestley (1926) the fatty substances in the stem in darkness do not move to the surface but are oxidized and deposited in the endodermis as a Casparian strip. In the stem in the light, fatty substances migrate immediately to the stem surface where they form the cuticle. At the inner walls of the endodermis fatty substances col-

lect and are oxidized because they come in contact with air from the large intercellular spaces of the cortex. Thus Priestley believes that in aerial stems the cortical oxygen supply is less than in roots and underground stems, hence the fats are not condensed but migrate to the epidermis to become a part of the cuticle. Priestley and his students also believe that there is less water loss in aerial stems where the cuticle is thick, hence condensation does not take place in the site of the future endodermis.

The behavior of the oxidation system of the endodermis is causally related to the appearance of this tissue; however, it is not possible as yet to propose a complete theory as to the function of the oxidation system in bringing about the formation of a differential tissue between stele and cortex. The following are proposed as theories to explain the absence or irregular appearance of the endodermis in aerial stems. (1) Autoxidation is catalyzed and carried to completion without the deposition of intermediate products. (2) Some photocatalyst may be present which breaks up or accelerates oxidation by catalyzing the reaction of some constituent of the oxidation system. (3) There may be less peroxide formed in aerial stems in the period of active growth, or peroxides may be immediately decomposed so as to prevent the oxidation and condensation of unsaturated substances. (4) Antioxidants may be present in greater quantity or in a more active form in aerial parts of the plant. (5) Inhibitors in the form of antioxidants may be present in both aerial and subaerial stems but they may affect the light reaction and not the oxidation reaction in the dark. (6) The presence of antioxidants in vegetable oils and fats (Bradway and Mattill, 1934, and Olcott and Mattill, 1936) prevents autoxidation, and it is conceivable that there may be more antioxidants formed in the light than in the dark. (7) The distribution of unsaturated fats, or the nature of these fats, may affect the differentiation of the endodermis.

The fact that many monocotyledonous plants lack an endodermis in both subaerial and aerial stems, and that still others have an endodermis in aerial stems (Van Fleet, 1942), suggests that there must be some exact oxidation system responsible for endodermal differentiation. The fact that the Araceae in general lack an endodermis in stems regardless of their environmental position suggests an internal agency responsible for differentiation. In the Gramineae (Schwendener, 1890) the irregular and sporadic appearance of the "mestome sheath," an endodermal tissue, its absence in whole tribes and presence in others, is further suggestive of something more than the quantitative cortical oxidation and condensation of fats. If light and other external environmental factors were alone responsible for fat mobility then there should be uniformity in endodermal formation. The irregular appearance of the endodermis must be related to either (1) some variation in behavior of constituents, or (2) the irregular distribution of inhibitors to the oxidation reaction.

SUMMARY

Evidence obtained by the use of various indicators, numerous oxidants and antioxidants, substantiates the viewpoint that unsaturated fats associated with the endodermis autoxidize and undergo peroxidation to release an active form of oxygen. The peroxide formation by fats is construed as an oxidase system resulting in the oxidation and reduction of accompanying substances as well as the components of the system. Autoxidation is most rapid under alkaline conditions and in the absence of tannins, reducing agents and other inhibitors. Unsaturated bonds converted to peroxide linkages are believed to be the energy source for further desaturation and peroxidation. The release of active oxygen and the presence of unsaturated substances accelerate condensation reactions, and a polymerization of degradational products leads to the formation of a typical mature endodermis characterized by the Casparian strip or centripetal deposition in the walls.

The typical endodermis as a series of U-shaped cells, particularly in endogenous plants, is a result of intense oxidation in the outer tangential walls and concomitant condensation and polymerization along the radial and inner tangential walls. The greater prevalence of unsaturated substances in the outer tangential walls is directly correlated with more intense oxidative action in this region. The lack of thick cellulose lamellae in the outer part of the U-shaped endodermis is thought to be a result of the intense oxidation in this zone. The oxidation of unsaturated fats is believed to bring about the oxidation and destruction of other substances, notably cellulose or cellulose precursors. The endodermal cell may be thought of as a differential tissue in which the outer side has a high oxidation potential, and the inner zone is low in oxidative properties and possibly constitutes a zone of reduction.

Fatty deposition and oxidation in the endodermis are initiated opposite the phloem which accounts for

the early deposition of centripetal lamellae in the region of the phloem. Oxidative action comes later in the endodermis opposite the xylem than in the region of the phloem, and oxidation in some cells opposite the xylem is not confined to the outer tangential wall as in the case of the phloem but is found in and around all walls. The sustained oxidase activity in all walls of the endodermis opposite the xylem is the probable reason for the lack of centripetal deposition in these cells, thus giving rise to the typical "gap cell" so often associated with the xylem.

The endodermis as a differential between two widely different systems, the cortex and the stele, exhibits the characteristics of both systems, that is, the endodermis is more like the thin-walled cortical cells on one side and the thick-walled sclericycle cells on the other. Oxidation is more pronounced in the outer portion of the endodermis toward the cortex and is in general less intense in the stele or sclericycle. Unilateral deposition is related to differences in intensity of oxidation and deposition, and the U-shaped cells are thus indicative of the endodermis as a differential between two very different tissue systems.

The irregular distribution of the endodermis is believed to result from the behavior of the oxidation system herein proposed, and several theories are offered as to the function of the oxidation system in the formation of this tissue. The interrupted nature of the endodermis, its absence in aerial stems of many monocotyledonous plants and irregular appearance in dicotyledonous plants, are believed to result either from some variation in behavior of constituents of the oxidation system, or from the irregular distribution of inhibitors to the oxidation reaction.

THE EFFECTS OF AGE AND IRRADIATION ON CHROMOSOMAL ABERRATIONS IN ALLIUM SEED ¹

Charles Nichols, Jr.

ANALYSIS of chromosomal aberrations has become an important part of experimental cytology. Chromosomal rearrangements have been shown to be of considerable importance in relation to speciation (Dobzhansky, 1937). These changes are known to occur spontaneously in many organisms, but their frequency is very low, and for this reason they are difficult to study quantitatively. Aging, heat, irradiation, and hybridity bring about an increase in the frequency of structural chromosome alterations as well as an increase in the frequency of gene mutations. How these factors are related to one another and how they cause changes in the chromosome and gene mutation rates are not well understood. However, the fact that all these external agents cause similar changes suggests that a broad fundamental process is the primary cause of increases in mutation rates.

The present investigation deals with gross structural changes in the chromosomes of *Allium* induced by subjecting the dormant seed to the action of age and irradiation. Although the effects of these external factors have been studied by many investigators dealing with both plant and animal material, there are very few reliable data concerning the seed.

Cartledge and Blakeslee (1934) studied the effects of aging on *Datura* seed and Navaschin (1933) and Navaschin and Gerassimowa (1936) reported on the effects of aging on *Crepis* seed. Peto (1933) studied the effects of high temperature on the mutation rate in corn and barley seed. Schkwarnikow and Navaschin (1934) and Kirnossowa (1936) studied the effects of high temperature and moisture content on seeds of *Crepis*. However, none of these investigators give quantitative data on the number

of chromosome aberrations appearing immediately after germination. Gustafsson (1937) studied the effects of age, moisture, and X-rays on the seed of barley, and reports on the number of disturbed cells in the first mitotic divisions after germination. Nichols (1941) has reported on spontaneous aberrations and the effects of aging on *Allium* seed as determined from examination of the first mitotic divisions.

Dry seed have many advantages as material for experimental studies on chromosome behavior. Seeds are in a relatively dehydrated condition and physiological activity is at a minimum. Seeds of many plants can be kept viable for a number of years and thus the effects of aging may be investigated. Seeds are also more resistant to external agents such as heat and X-rays. This enables a wide range of treatments to be used when dealing with these external factors. Finally, the chromosomes are known to be in the resting stage in dormant seed, and thus any treatment applied to the seed must act on the chromosomes while in a relatively uniform condition.

In the experiments to be reported here seed of several different commercial varieties of *Allium cepa* L. were used. The seeds were obtained from a reputable seed company and represent crops from the years 1935, 1936, 1937, 1938, 1939, and 1940. All seeds were germinated at room temperature on moist filter paper in Petri dishes. Germination took place in three to four days depending on the condition and the treatment of the seed. Cells in the very shortest root tips contain no division figures. For this reason it seems probable that the first visible signs of germination in *Allium* are the result of cell expansion. An examination of root tips of different lengths indicated that the first mitotic activity was to be found in root tips 2-4 mm. in length.

¹ Received for publication July 1, 1942.

Primary mitotic divisions may be distinguished from secondary and later divisions by the nature of the aberrations observed. In the primary divisions chromosome bridges are accompanied by acentric fragments. The fragments in primary divisions are very definite in shape and outline, while in secondary divisions they appear as micronuclei in various stages of disintegration. Bridges and fragments occurring during the last division preceding dormancy would appear as secondaries in the first division after dormancy. However, the frequency of such aberrations in the last division before dormancy is probably very low. The few cells observed which contained bridges without fragments are probably due to the fact that the fragments were too small to be seen.

TABLE 1. *Distribution of the various types of aberrations observed.*

Types of aberrations	Number	Per cent
Chromatid aberrations:		
Bridge plus fragment	44	1.4
Bridge without fragment	18	0.5
Acentric rod fragment	100	3.2
Acentric dot fragment	12	0.3
Chromosome aberrations:		
Bridge plus fragments	781	25.0
Bridge without fragments	218	7.0
Paired acentric rod fragments.....	1135	36.4
Paired acentric dot fragments.....	801	25.7
Ring chromosomes	4	0.1
	3113	99.6

All root tips were fixed in a 3:1 alcohol-acetic fixative and stained according to the Feulgen technique. Smear preparations were used entirely and anaphase figures were analyzed in most cases, since chromosome bridges and fragments are most readily detected at this stage. Wherever possible 100 figures were analyzed on each of three slides. A total of 21,808 cells was tabulated and 3,113 aberrant cells were recorded. The distribution of the various types of aberrations is given in table 1.

EFFECTS OF IRRADIATION AND AGE ON DRY SEED.—Ten lots of dry seed consisting of five different varieties and two age classes in each variety were selected for irradiation. The dry seeds were given a dose of 2000r at an intensity of 100r/minute. The irradiated seeds were divided into three equal parts. One part was placed in Petri dishes to germinate immediately after treatment and roots 2–4 mm. in length were fixed. In all cases the irradiation resulted in a significant increase in the frequency of gross chromosomal aberrations. The results of this experiment are presented in table 2. The object of this analysis was to determine whether there were any varietal differences in sensitivity to X-rays and whether the age of the seed had any effect on sensitivity. Four of the five varieties show about the same sensitivity to X-rays, but the variety Sweet Spanish appears to be somewhat less sensitive. This fact is of interest because this variety shows a higher frequency of aberrations in the controls than do the other four varieties.

In order to determine whether sensitivity to X-rays is in any way related to the age of the seed the correlation between age and X-ray sensitivity was calculated for the ten lots of seed tested. A coefficient of +.12 indicates that there is no significant correlation between these two factors and suggests that, while both age and irradiation cause increases in the frequency of chromosomal aberrations, the causal mechanisms may be different.

Of the remaining two lots of seed which were irradiated, one part was allowed to remain dry at room temperature for two weeks before germinating, and the third part was kept dry at room temperature for four weeks before being placed in Petri dishes to germinate. In this way it was possible to determine whether there were any secondary after-effects of irradiation such as have been reported by Gustafsson (1937). The results are presented in table 3. It is quite evident that there is a definite after-effect following X-ray treatment of dry seed which causes a marked increase in the frequency of chromosomal disturbances. It is further evident that in certain cases this after-effect is quite rapid, since the great-

Mean per cent aberrant cells for all material examined four weeks after irradiation:						
23.53 \pm .791.						

est increase in frequency of aberrations takes place in the first two weeks following irradiation, and little change is observed during the third and fourth weeks. Only one out of the ten lots of seed thus tested failed to show after-effects. This one was the only lot of fresh seed used, Ebenazar 1940.

A second series of tests was carried out to determine whether the increase in aberrations with delayed germination following X-ray treatment was in any way associated with the age of the seed. For this purpose one lot of five-year old seed and two lots of fresh seed were used. Following an X-ray dose of 2000r, part of the seeds in each lot were germinated immediately, and the remaining seeds were germinated at five-day intervals for a period of three weeks. The results are given in table 4.

It is apparent from these results that in aged seed, in addition to aberrations caused by any direct-hit mechanism of the X-rays, there are set in motion other changes in the cells which continue to cause chromosome breakage for some time after irradiation has ceased. The fact that fresh seed does not show this after-effect would indicate that the physiological condition of the cells is intimately associated with the production of after-effects following irradiation with X-rays.

By varying the treatment of the seed following irradiation it is possible to obtain further evidence that the physiological condition of the seed is closely

associated with the cytological after-effects resulting from delayed germination. A single lot of seed was given an X-ray dose of 2000r. Immediately following irradiation the seeds were divided into six equal parts and treated as follows: (1) germinated immediately, (2) kept seventy-two hours dry in the refrigerator, (3) kept seventy-two hours moist in the refrigerator, (4) kept seventy-two hours dry at 60°C., (5) kept seventy-two hours dry at room temperature, (6) kept 144 hours dry at room temperature. This experiment was carried out in duplicate, and the results are summarized in table 5.

The seeds kept moist at the low temperature show a significant increase in the number of aberrant cells. This is presumably not an effect of the low temperature, since the seeds kept dry at that temperature did not show any increase. It may be due entirely to the moisture or to an interaction of moisture and low temperature.

Discussion.—The results of the preceding experiments pertaining to the frequencies of chromosomal aberrations in dormant seed may shed some light on several points of theoretical interest to the experimental cytologist. It is a generally accepted fact that the actual frequency of breaks in X-rayed material is very much greater than can be determined by analyzing chromosome aberrations. This is due to the fact that in the majority of cases single breaks in a chromosome are followed by a re-fusion of the

TABLE 4. *Comparison of the effects of delayed germination, as shown by per cent aberrant cells, following irradiation of one lot of aged seed and two lots of fresh seed.*

broken ends in the original position, leaving no evidence of breakage. Sax (1939) has discussed this point in a paper dealing with the time factor in the production of chromosome aberrations by X-rays.

In dealing with chromosome aberrations due to aging, the exact mechanism causing chromosome breakage is not known, but it is apparent that one cannot speak of "one hit" and "two hit" aberrations in the same sense that these terms are used in connection with X-ray-induced aberrations. Whatever the mechanism may be, it is similar to irradiation in that it probably produces a great many more breaks than can be detected by an analysis of chromosome aberrations at anaphase. Of interest in this connection is the question as to how long broken ends of chromosomes can remain open. In *Tradescantia* microspores Sax (1939) finds that broken ends remain in an unstable condition for not more than one hour before healing. Stadler (1932), on the other hand, believes that the broken ends of acentric fragments remain unhealed and capable of re-fusion for several cell generations. Recent evidence from work on X-ray-induced structural changes in *Drosophila* (Muller, 1940; Kaufmann, 1941) indicates that broken ends in sperm nuclei remain unhealed for as long as a month. Muller reports that the primary effects of irradiation (breakages) accumulate in the spermatozoa until the time of fertilization, regardless of how long this period may be.

In connection with aberrations arising as a result of aging or other treatments of dry seed, three hypotheses are possible: first, breakage and re-fusion may be occurring at random during the period of dormancy; second, breakage may be occurring at random, but re-fusion may not take place until the initiation of activity at the time of germination; third, breakage and re-fusion may not occur until the time at which germination starts.

If broken ends of chromosomes in the resting nuclei of dry seed of *Allium* remain unstable and capable of re-fusion for only a short time, then the actual frequency of breakage in these chromosomes must be very high in order that two independent

breaks occur within the given time limit and thus give rise to reunions which result in visible aberrations. It would seem more likely that the broken ends of chromosomes in dormant seed can remain in an unstable condition for long periods of time. Although certain difficulties in the material have prevented an adequate test of the time factor in the production of X-ray-induced aberrations in *Allium* seed, it is not inconceivable that the broken ends may remain open throughout the period of dormancy of the seed. All the reunions may occur at the time when germination is initiated.

It has been suggested that aberrations observed in aged seed might be due to the accumulation of the effects of natural radiation, but Navaschin (1933) and others have shown that this cannot be the case. The results of many investigators on the relationship of X-ray dosage to percentage of structural changes has led to the belief by some that a direct-hit mechanism is involved. However, the fact that agents other than X-rays can produce the same effects leads one to question the validity of the direct-hit mechanism as of general application. It is probable that X-rays produce two independent changes: a direct-hit mechanism causing chromosome breakage and fusion, and a physiological effect. In fresh seed the physiological effect does not alter the frequency of chromosome breaks. In aged seed, however, the physiological effect results in an increase in the frequency of chromosome breaks. Breaks resulting from the physiological effects of the X-rays are superimposed on the breaks resulting from the direct-hit mechanism. Changes in the coiling cycle causing stresses on the chromosomes can hardly be involved in the dry seed, since the chromosomes are in the resting stage and in a relatively relaxed condition. It is possible that the frequency of chromosomal aberrations is to a certain extent genetically controlled. Beadle (1937) has shown that the gene for sticky chromosomes in maize causes an increase in the frequency of chromosomal rearrangements. The most plausible explanation seems to be that internal changes in the physiological condition of the cells are responsible for chromosome breakage (Schkwarnikow and Navaschin, 1934; Stubbe, 1936).

In connection with changes in the physiological condition of the cells, there is some disagreement as to whether direct changes in the chromosomes cause the increase in break frequency (Gustafsson, 1937) or whether the chromosomes are indirectly affected as a result of a general upset in the metabolism of the cells (Schkwarnikow and Navaschin, 1934). At present, experimental proof of either hypothesis is lacking. The investigations of *Allium* seed seem to point in the direction of a general physiological change which indirectly affects the chromosomes.

SUMMARY

Chromosomal aberrations appearing in the primary divisions of root tip cells in several varieties of *Allium* have been analyzed. Aging of the seed was

found to result in an increase in the number of aberrant cells. Irradiation of the dry seed also causes an increase in the number of aberrations. No correlation was found between the age of the seed and its radio-sensitivity, indicating that possibly two different mechanisms may be involved.

Delayed germination of seeds following irradiation causes a significant increase in the number of aberrations except in cases where fresh seed is used. The number of aberrations is also found to be greater

when the moisture content of the seeds is increased during the period of delayed germination.

In addition to the aberrations arising as the result of "direct hits" following irradiation, it is pointed out that physiological factors such as age of seed and moisture content are of importance in bringing about structural changes in the chromosomes.

THE TELOME THEORY AND THE ORIGIN OF THE STAMEN¹

Carl L. Wilson

It is becoming widely recognized that the generally held concept of the essential organs of the flower as modified foliar appendages rests upon a most insecure foundation. This view of the nature of the carpel and the stamen, which may be termed the "classical" theory of the fundamental nature of the floral organs, has prevailed since the time of Goethe and A. P. De Candolle, and has been supported by many workers since that time (Arber, 1937). Certain aspects of vascularization of the carpel may be adduced in support of this point of view, but these facts may also be interpreted merely as indicating parallel development in the relationship of leaves and floral organs; we must delve deeper to understand the nature of appendages in general.

Information has become available in recent years which will permit of a more plausible hypothesis of the fundamental nature, not only of the plant body of the higher vascular plant but also of the flower

itself. Studies on fossil remains of early and simple land plants show organisms with no differentiation of leaf and axis, but rather a simple and commonly dichotomously branched body of indeterminate growth; certain of the terminal branches, the fertile telomes, bore terminal and solitary sporangia, while other branches were sterile. Information derived from such early land plants, from the ferns and fern-like plants of the Paleozoic, and from modern ferns has shown that the fern leaf, and that of the Pteropsida in general, may well have developed from a dichotomous branch system which has become webbed and flattened and from sympodial development has moved to monopodial growth with lateral branches on a main axis. No extensive account of the telome theory, which describes the plant body in terms of a branching axis, will be attempted here; the reader is referred to Bower (1935) and Eames (1936).

In attempting to account for the origin of the flower on the basis of the telome theory, we may postulate that the sporangium-bearing branches in ancient vascular plants were at first photosynthetic,

¹ Received for publication July 8, 1942.

The writer has been privileged to discuss the subject matter of this paper with Dr. A. J. Eames of Cornell University, to whom he is indebted for aid in the clarification of several of the viewpoints here presented.

Fig. 1-16.—Fig. 1-5. Hypothetical reconstruction of the evolution of carpel, stamen, and leaf, on the basis of the telome theory.—Fig. 6. *Protopteridium hostimense*, sporangia.—Fig. 7. *Pseudosporochnus Krejci*, sporangial cluster.—

but that later this process became largely or entirely restricted to the forerunners of the modern leaf; the processes of reproduction and food manufacture in the ancestors of the modern flowering plant were early separated (fig. 1). Fertile branch systems of two kinds became distinguished, and following such processes as webbing, fusion, and reduction, one of these became the carpel, the other the stamen. Evidence bearing upon the evolution of these floral organs may be found in the papers by Hunt (1937) and Wilson (1937). The evolution of the terminal portions of the plant body is shown schematically in figures 2 to 5. The primitive foliar organ is shown to have developed through stages including flattening, webbing, and fusion of sterile telomes. Similarly, a group of fertile telomes became webbed and fused to form the carpel, which later folded along the margins, enclosing the sporangia. The stamen, likewise, is the result of reduction from a system of dichotomously branched fertile telomes, or even from a portion of such a system. From such a branch system the stamen undoubtedly evolved in different ways; in the scheme shown here, the ultimate fertile telomes are first shown to fuse in pairs (fig. 2, 3); then following reduction or fusion of the telome stalks, the paired sporangia became aggregated into groups of four, a prototype of the modern anther (fig. 4, 5). The remaining telomes of the system first became sterile, and finally disappeared.

Since our knowledge of the early forms of plant life of the Paleozoic shows that spore-producing structures antedated any differentiation of leaf and stem, the problem of the stamen then becomes not how a stamen may have become modified from a leaf but how a stamen may have arisen from a branch system possessing terminal sporangia, a system existing before leaves had evolved.

We have indicated the possible origin of the stamen, together with other organs of the plant, from a highly reduced branch system; it now remains to determine whether this structure has retained in its modern form any evidence of its ancestral history. In consideration of the undoubted great age of the race of angiosperms, of the ephemeral nature of this organ, and of the great reduction which the sporangial branches of ancient plants have undergone, it is too much to expect that unimpeachable proof will be found in the external morphology or internal structure of the stamen which will determine for all time the problem of the origin of this structure. A new method of approach to the problem has been used by Satina and Blakeslee (1941) in an investigation of the histogens which give rise to the leaf and floral organs in periclinal chimeras of *Datura Stramonium*. They found that the ontogeny of the

stamen resembles that of the shoot apex rather than that of leaf, sepal, or petal, and conclude that the stamen is a reduced axis. Aside from such studies as these, the chief lines of evidence, for the present at least, must lie in the vascularization of the stamen—of the filament and connective. A preliminary and by no means exhaustive survey of the nature and direction of the course of the vascular bundles of stamens makes possible an estimate that in probably 95 per cent of angiosperms the stamen is supplied with a single vascular bundle which traverses the filament. This bundle may end at the base of the anther or may ascend the connective for some distance, to end blindly at a greater or lesser distance from the apex. In certain other forms deviations from this general plan exist which possibly may be of significance in a consideration of stamen origin and evolution.

In any discussion of stamen phylogeny it should be emphasized that the stamen, as well as the carpel and leaf, may well have originated not only at different times but also along different lines. In the hypothetical reconstruction of the flower shown in this paper, a four-celled anther is shown to have arisen from a branch system by sterilization and reduction. The anther thus constituted may have been erect on the telome stalk, or inverted. That such branch systems existed is well known. Figures 6 and 7, from Kräusel and Weyland (1933), illustrates sporangia borne erect on dichotomous branches. This condition was common, not only in the Psilophytales, but also, in a somewhat modified form, in a great series of plants more complex than these; dichotomy, or terminal sporangia, or both, seems to have existed as a general trend throughout the middle and later Paleozoic. Figure 8 is a portion of a well-known restoration of *Psilophyton princeps* from Dawson (1888). The nature of the reproductive structures of this plant as described by Dawson (1871) is entirely confirmed by Halle (1916) who, however, refers the fructifications of the plant to the genus *Dawsonites*. It is probable that the sporangia were borne in pairs, at the apices of fertile telomes, and that the fertile branch system divided dichotomously several times. The sporangia were lax or pendulous, tending to bend back upon the fertile telome stalks which bore them. This tendency is carried further in *Dawsonites bohemicus* as illustrated by Kräusel and Weyland (1933). The sporangia of this poorly understood fossil appear to be strongly reflexed and perhaps fused with the stalks which bear them. Such pendulous sporangia, fused with their sporangial stalks, could well have given rise to those types of anthers in modern forms which appear to be borne marginally rather than terminally. A reduction of the telomes forming the

Fig. 8. *Psilophyton princeps*, portion of fruiting structure.—Fig. 9. Hypothetical primitive stamen as reduced from a double dichotomy.—Fig. 10. Stamen and vascularization, *Tilia americana*.—Fig. 11. Single stamen, *Penaea mucronata*.—Fig. 12, 12a. *Enallagma megaphylla*, entire stamen and cross section.—Fig. 13a-d. Diagrams to show origin of connective in stamen in which the anther is suspended.—Fig. 14, 14a. Stamen and cross section, *Bauhinia mollicella*.—Fig. 15, 15a, 15b. *Passiflora vitifolia*, stamen and cross sections at levels indicated.—Fig. 16, 16a, 16b. *Cobaea scandens*, stamen and cross sections.

last two dichotomies in such a form as Dawson's *Psilophyton princeps* may well have given rise to the hypothetical stamen diagrammed in figure 9, which approximates in many respects the condition found in certain modern stamens.

Since such forms existed, and may have represented strong trends in ancient plants, it should be permissible to interpret certain conditions found in living species in the light of the past. While there is considerable variation in the form of the small stamens of *Tilia americana* L., a number in each flower assume the shape shown in figure 10. The filament tends to bifurcate at the summit, each branch bearing a pair of sporangia. The single vascular bundle occasionally fades out at the point of division of the filament, but also commonly divides, each branch passing for a short distance into the filament branches. This condition may well represent a double dichotomy of a branch system, here reduced to a single dichotomy. A similar condition is also to be found in the stamen of *Penaea mucronata* L. (fig. 11), in which the paired sporangia are located toward the base of a well developed connective. The single bundle enters the filament and passes to the top of the connective, dichotomizing at the apex. The sporangia in this species may have migrated to the base of the connective, or the connective may have become greatly enlarged.

The vascular supply of the stamen of *Enallagma megaphylla* (D.Sm.) Standl. is clearly dichotomous. The anther is essentially of the suspended type (fig. 12), attached to the filament but a short distance below the apex. At the point of attachment the filament bundle dichotomizes, sending two bundles downward in the connective almost to the apices of the anther halves. This condition is clearly revealed by a cross section of the entire anther (fig. 12a) taken from the region indicated by the dotted lines. It should be noted that here the paired sporangia on either side of the filament remain discrete; the walls between the pairs do not break down, and, as in many other species, the anther contains four pollen sacs (sporangia) at maturity. The diagrams in figure 13, a-d, show how this condition could have arisen. The stalks of two pairs of sporangia first became reduced, so that the sporangia were almost sessile and were contiguous. Each pair of sporangia then became folded back upon a penultimate unit of the branch system and became fused with this unit. If these latter units then became pendulous, the condition exhibited by *Enallagma* would have arisen.

Extensive modifications of this dichotomous system may possibly be illustrated by the course of the staminal vascular tissues in *Bauhinia mollicella* Blake (fig. 14),² *Passiflora vitifolia* HBK. (fig. 15) and *Cobaea scandens* Cav. (fig. 16). In all of these forms the filament is attached to the anther midway between the apex and base of the anther; in *Bauhinia* and *Passiflora* the filament is dorsi-fixed, in

Cobaea the filament is attached on the ventral or adaxial side. The general trend of vascularization is the same in all; a single vascular bundle passes up the filament and divides into three parts in the connective in the region of attachment of the filament. Two of these branches proceed downward in the connective on either side, the third passes upward, apparently as a continuation of the main bundle of the filament, except in *Cobaea*, in which it appears as a branch of one of the downwardly directed bundles. Cross sections of the anthers are shown in figures 14a, 15a, 15b, 16a, 16b, taken from the regions indicated by the dotted lines. Several interpretations of this condition as a modification of the dichotomously branching pattern may be advanced, and one of these is diagrammed in figure 17, a-e. In figure 17a is shown a terminal branch system consisting of four fertile telomes, in which the two penultimate units of the system have become reduced to the extent that the telomes arise from the same point. In 17b the telomes have become reflexed and the sporangial stalks partly fused. In 17c and 17d fusion has proceeded farther; the paired telomes on either side of the main stalk of the system have fused together, and these in turn have become partly fused with the basal stalk. If, now, the sporangial pairs should become compressed and elongate acropetally, they would become adherent to the stalks on which they are borne, and the vascular bundles would come to lie in the position shown in figure 17e.

✓The problem of the stamen with three traces has always attracted considerable interest, and Eames (1931) cites certain families in which this condition occurs. This situation may well be primitive, as Eames states, and the three-trace system may have arisen through a series of modifications of a dichotomous branch system as shown in figure 18, a-d. In figure 18a is shown the system previous to reduction. In 18b the basal stalk of the system has dropped out, and six central units of the system are about to fuse. In 18c complete fusion has taken place, accompanied by reduction and sterilization which has led to the disappearance of the central sporangia of the branch system. Further sterilization and reduction would result in the three-trace system shown in figure 18d.

The staminal vascularization of *Fremontodendron mexicanum* Dav. (*Fremontia californica* Torr. var. *mexicana* Jepson)³ and *Cassia undulata* Benth. may well represent reductions from this hypothetical scheme. *Fremontodendron* (fig. 19) possesses a true three-trace system, each bundle arising independently from the stele. The central trace traverses the entire length of the connective, which extends into a point beyond the paired sporangia. Here the central bundle dichotomizes. The lateral traces each give off a bundle at the base of the anther, and these bundles, branching somewhat, pass downward into the connectives of the paired thecae (fig. 19b). As the lateral traces move upward in the connective

Fig. 17-21.—Fig. 17a-e. Hypothetical course of evolution of a stamen with marginal sporangia.—Fig. 18a-d. Hypothetical origin of a three-trace stamen from a dichotomous branch system.—Fig. 19, 19a, 19b. *Fremontodendron mexicanum*, stamen and cross sections.—Fig. 20, 20a. *Cassia undulata*, stamen and cross section.—Fig. 21. Cross section of stamen of *Cassia marginata* close to apex of anther.

they give off a series of branches, like the veins of a feather, which pass into the tissue of the connectives on either side (fig. 19a). While many aspects of vascularization in this stamen remain to be explained, the nature and course of the main bundles may be found to be most significant in connection with the problem of stamen phylogeny after the stamens of a great series of forms have been studied from a comparative standpoint. The three main bundles traversing the connective may be held to represent the three bundles shown in figure 18d, and the bifurcation at the apex of the central trace a remnant of the condition shown at the apex of the central bundle of figure 18c, after the sporangia have disappeared from that portion of the branch system.

In the larger of the two sets of stamens of *Cassia undulata* (fig. 20) the course of the vascular bundles in the connective is similar to that of *Fremontodendron*. The filament contains but one large horseshoe-shaped bundle, possibly the result of the fusion of three. This bundle divides into three at about the point of insertion of the filament on the anther. The central trace does not dichotomize but passes upward in the center of the connective, to fade out at the very apex of the anther. The lateral bundles are at first quite strong (fig. 20a), giving off connections into the tissue of the connective on either side; later, they become weaker and disappear at a level below that of the disappearance of the central bundle. Certain other species of *Cassia* show this same vascular plan with some modifications, a plan which may be looked upon as the result of the partial fusion of the bundles of an originally three-trace system. Among the more interesting deviations from this plan is that found in *Cassia marginata* Willd. (fig. 21). The three main bundles closely approach

each other near the top of the anther. At this point the anther divides into three parts, a bilocular region on either side with an apical projection between. The central bundle remains in this projection, while the lateral ones pass into the connectives of the paired sporangia on either side. This condition is essentially that found in the hypothetical reconstruction shown in figure 18d.

The conditions just described by no means exhaust the deviations from the common condition of a single unbranched bundle supply in the filament and connective. In many species these take the form of one or several branches arising irregularly from this central bundle at various points in the filament and connective; while these conditions may be related to reduction from the three-trace system, either reduction has proceeded too far, or intermediate stages are lacking, so that a definite interpretation is lacking in these cases.

Discussion.—The present paper is by no means intended as a definitive and final pronouncement upon the origin and evolution of the stamen. It is, rather, in the nature of a progress report, calling attention to certain aspects of stamen vascularization which may be of significance in a renewed attempt to understand the nature of the stamen in the light of fresh viewpoints arising from an increased knowledge of ancient plants. The evidence thus far available for the origin of the stamen in the light of the telome theory is by no means conclusive. On the other hand it seems desirable to emphasize the fact that the classical theory of the origin of the floral parts has come to us largely as the result of certain metaphysical concepts of Goethe (Arber, 1937), and is supported chiefly by evidence derived from teratological phenomena, a type of evidence which has long fallen into disrepute.

Here, then, is a concept of the stamen different from that of a modified foliar appendage; moreover, acceptance of the telome theory with respect to the stamen as a working hypothesis does not invalidate our generally held view of the flower as an axis with highly modified and specialized leaf-like appendages; we may now regard the stamen, and the carpel as well, not as modified leaves but as reduced branch systems, homologous with leaves of a similar origin. Floral organs resemble leaves, and their vascularization is similar because they have evolved in a similar way.

It is possible that the nature of the primitive stamen is still unknown, although it is probable that a synangium of four sporangia is a very ancient structure and was derived from the reproductive structures of ancient lines which gave rise to such groups as the flowering plants, the ferns, seed ferns, and the Cordaitales. Since the nature of the primitive stamen is not positively known, it is not possible to interpret finally all of the various aspects of form in the modern stamen. The nature of the connective, for example, is not clear; a working explanation may be reached, however, after consideration of the lax or pendulous nature of the sporangia in certain ancient forms. If these became reflexed and fused with their telome stalks, the marginal position of the pollen sacs with respect to the connective in great numbers of species may be explained. Undoubtedly, also, secondary vascular bundles, whose positions are not significant from a phylogenetic viewpoint, have arisen in connection with nutrition and translocation. It is possible that the vascular anatomy of the stamen may never be interpreted to the degree, for instance, that we now understand the relation between carpel and leaf. In the flower as a whole, such problems as the cauline ovule, free central placentation, epigyny, the reduction and disappearance of floral parts, the interpretation of vestigial structures, the determination of phylogenetic relationships—these and others have been solved or partly solved by the anatomical method.

This, however, is essentially comparative in its approach; structures in a large range of forms have been studied before interpretations could be made and conclusions drawn. It must be likewise with the stamen, with the added great difficulty that this organ is much more reduced, both externally and with respect to its vascular tissues, than any other organ of the flower.

SUMMARY

The "classical" theory of the nature of the floral organs as modified foliar appendages is attacked, especially from the standpoint of its inadequacy in explaining the origin of the stamen. A concept of the evolution of the stamen based upon the telome theory is presented. This viewpoint considers that the anther is a synangium of four sporangia, and that this synangium, together with the filament and connective, has arisen from a dichotomous branch system with terminal sporangia, following such processes as fusion and reduction of the fertile telomes (sporangia and their stalks) and other parts of such a system. The theory receives a measure of support from paleobotanical studies upon the reproductive structures of certain ancient and primitive plants of the Paleozoic. It is further supported by the staminal vascularization of certain selected living angiosperms.

It is suggested that the vascular bundles and their connections in these forms may represent vestiges of the vascularization of such ancient branch systems. An understanding of stamen morphology may be attained by considering the filament as the basal part of such a system, the connective consisting of modified subsidiary branches to which the reflexed sporangia have become fused. The vascularization of the three-trace stamen may similarly be derived from that of a dichotomous branch system following extensive reductions and fusions.

AUXIN CONTENT OF MAIZE KERNELS DURING ONTOGENY, FROM PLANTS OF VARYING HETEROTIC VIGOR ¹

G. S. Avery, Jr., J. Berger, and B. Shalucha

A METHOD involving alkaline hydrolysis has been developed for the rapid and total extraction of auxin from dormant endosperms of maize and other cereal grasses (Avery, Berger and Shalucha, 1941). Upon preliminary tests this method was found to give extremely high yields of auxin from freshly harvested immature corn kernels. Other tests showed that these yields were much higher than those obtainable with repeated alcohol or ether extractions, a fact previously established for dormant corn. The method was, consequently, regarded suitable for studies on the rate of auxin accumulation in corn kernels during their ontogeny. The procedure arbitrarily differentiates between free auxin and precursors of auxin, the former being that detectable before alkaline hydrolysis, the latter the increase obtainable upon alkaline hydrolysis. It is noteworthy that while alkaline hydrolysis has not proved satisfactory for a number of green tissues on which it has been tested, it is highly effective as a method of extracting auxin from growing kernels of corn.

The objects of this study were as follows: (1) to determine the extent of auxin storage at intervals in the ontogeny of the kernel; (2) to determine whether marked differences in vegetative vigor of plants are reflected in equally marked differences in the auxin content of the kernels they bear—thus the study concerned the possible effect of growth vigor on auxin accumulation in storage tissue, not the effect of auxin on growth. In the course of these experiments kernels from vigorous hybrids and polyploids of varied genetic origin and makeup were investigated, and compared with kernels from less vigorous inbreds. Although some of the evidence presented might indicate a relationship between heredity and auxin storage, the experiments were not designed with this in view, and evidence along such lines is considered inadequate for any generalizations.

Previous work on the ontogeny of maize (Laibach and Meyer, 1935) and on the growth of *Epilobium* hybrids (Graze and Schlenker, 1936) in relation to auxin content was done before quantitative extraction procedures and refined assay methods were available. Goodwin (1937) has reported that by the diffusion technique the relative concentration of auxin in leaves of *Solidago sempervirens* is consistently higher than in *S. rugosa* or the hybrid between them.

Hatcher and Gregory (1941), employing water as a solvent for extraction of auxin from kernels of winter rye during their ontogeny, report auxin content to increase rapidly from a very low value at time of pollination to a maximum five to six weeks later.

¹ Received for publication July 10, 1942.

We are grateful to Miss Mary Hickox for carrying out a considerable number of assays, and for her general interest in the problem.

At maturity the content had decreased to ca. 12 per cent of the maximum.

MATERIALS AND METHODS.—The stages of development of the corn kernels which were used and the ears from which they were taken, are shown in figure 1. Table 1 gives the varieties etc. used, dry weights, per cent dry matter and source. It is a pleasure to acknowledge the cooperation of E. B. Clark, D. F. Jones, John Shafer and L. F. Randolph in supplying at intervals the freshly harvested ears of corn in various stages of development. All plants were field grown.

Whole ears of corn were harvested in every instance and transported by motor car to the laboratory. The only exception was the Cornell material

Fig. 1. Above, corn kernels at the stages assayed for auxin precursor and free auxin. Below, ears from which the above kernels were taken; stages left to right, silk, blister, milk, dough, dormant.

TABLE 1. Per cent dry matter and dry weights of corn kernels at the different stages of development studied. The first eight samples were obtained from E. B. Clark, Associated Seed Growers, Milford, Conn., and all possess sugary endosperms. The last three samples were obtained from D. F. Jones, Conn. Agric. Exper. Sta., New Haven, Conn., and possess a soft dent endosperm, characterized by a small amount of corneous endosperm and a larger proportion of soft starch.

which was brought directly by train from Ithaca. The latter was approximately eighteen hours from field to laboratory, the former only two hours. Kernels from each ear of corn were assayed immediately, or whole ears were kept for not more than three to four days at 2°C. until extractions and assays could be made; proper precautions were taken to prevent desiccation. It was of course physically impossible to make all auxin assays on the day of harvest, since it would have involved 100 to 150 dozen test plants.

Crushed tissues were never stored, i.e., only the whole ears were stored, and such storage might be suspected of resulting in variable alterations in

yield, but this did not prove to be the case. Fresh corn, stored as above for as long as one week, did not show any appreciable increase or decrease in total yield, or in proportion of precursor to free auxin.

The methods of auxin extraction and assay used in this study have been reported in full (Avery, Berger, and Shalucha, 1941). Because of the exploratory nature of the study and the large number of assays involved, only six *Avena* test plants were used per dilution (instead of the usual dozen). However, this made possible the testing of a number of dilutions at one time, and thus expedited the finding

TABLE 2. Sample calculation of auxin yields for kernels of the variety Country Gentleman in the late milk stage.

Treatment	Total volume in cc. of agar- extract mixture from 1 gm. fresh tissue	<i>Avena</i> curvature in degrees (deseeded method)	Millions of TDC or tens of micrograms of indoleacetic acid		
			Per gram fresh wt.	Per gram dry wt.	Per kernel
Water extraction (free auxin)	200	13.8
	400	7.3	0.29	0.7	0.05
Alkali hydrolyzed (total auxin)	4000	29.7
	8000	19.0 ^a	15.0	38.0	2.9

^a Degrees curvature × agar volume in cc. × 100

Using the formula $\text{TDC/gram} = \frac{\text{Degrees curvature} \times \text{agar volume in cc.} \times 100}{\text{Weight of tissue in grams}}$, we have in this case $19 \times 8000 \times$

$100 = 15$ million TDC/gram fresh weight. The values 38 and 2.9 are calculated from the above and the data in table 1: per cent dry weight of kernel = 40, and dry weight of kernel = 75 mg.

of dilutions which gave curvatures in the proportionality range. Duplicate assays on representative

samples showed experimental variation of approximately 20 per cent, which is the normal variation in the *Avena* technique.

Values for "free" auxin content were obtained as follows: kernels were removed from the central portion of the ear and ground with a pestle; 0.5 gm. of this tissue was extracted with 10 cc. of water at approximately 25°C. for fifteen minutes, and the clear centrifugate of this suspension was assayed by the deseeded *Avena* method.

Values for "total" auxin content (auxin plus hydrolyzed auxin precursor) were obtained as follows: 0.25 gm. of ground tissue obtained as above was heated in 25 cc. of M/20 borate buffer, pH 9.6, at 120°C. for fifteen minutes. This was then neutralized to pH 6, and the clear centrifugate assayed.

The auxin precursor present in a given sample of tissue is determined by subtracting the amount of free auxin from the total auxin content after hydrolysis. The so-called precursor is an as yet unidentified compound (or compounds) which upon alkaline hydrolysis yields auxin. There is no appreciable conversion of precursor (less than 2 per cent) to free auxin during the five-hour deseeded *Avena* assay. Two per cent of the precursor yield is rarely of sufficient magnitude to affect the significance of the free auxin values. A simple calculation by the reader will make it clear wherever this has occurred.

TOTAL AUXIN IN WELL-KNOWN VARIETIES OF CORN DURING ONTOGENY.—Figure 2 shows the quantitative occurrence of auxin and auxin precursor in kernels of the varieties Country Gentleman and Golden Cross Bantam at different stages of development. The most striking fact is the overwhelming predominance of auxin precursor over auxin. The free auxin is never greater than 12 per cent of the total, and at the peak stages it constitutes not more than 3 to 6 per cent of the total.

On a dry weight basis it may be noted that the peak of total auxin content occurs at the blister stage of Country Gentleman, and not until the late milk stage for Golden Cross Bantam; whereas on a per kernel basis both varieties reach their peak at the late milk stage.

In the case of Country Gentleman both total auxin content and dry matter increase approximately ten-fold from silk to blister stage. From this peak to dormancy, dry weight increases another four-fold and total auxin concentration decreases to one-fourth its peak value. It appears, therefore, that in Country Gentleman auxin and dry matter increase together up to the blister stage, and, from this stage to dormancy, dry matter continues to accumulate, but total auxin apparently does not.

TOTAL AUXIN IN CORN INBREDS AND HYBRIDS DURING ONTOGENY.—The objects of the experiments reported in this section were: (a) to study the rate of auxin accumulation in kernels of inbreds and hybrids during their ontogeny, and (b) to determine whether marked differences in vigor of plants are reflected in equally marked differences in the auxin content of the kernels they bear. It should be pointed

Fig. 2-3.—Fig. 2 (above). Occurrence of auxin precursor and free auxin in kernels of "Country Gentleman" corn from time of pollination (silk stage) to maturity; "Golden Cross Bantam" from the milk stage to maturity. Both of these varieties possess a sugary endosperm.—Fig. 3 (below). Occurrence of auxin precursor in kernels of hybrid and inbred corn at different stages in development. Pedigrees 77, 75, 14 and 5 possess sugary endosperm; C-14 and 677 have starchy endosperm.

out that all the kernels from hybrid plants, reported in this part of the study, were themselves F_2 rather than F_1 kernels. This should be noted in contrast to the data in table 4.

Fig. 4. Occurrence of free auxin in kernels of hybrid and inbred corn at different stages in development. See legend of figure 3 for endosperm types.

In the graphs of figure 3, auxin precursor of three sets of inbreds and hybrids is plotted on a concentration and content basis. The former represents concentration per unit weight of tissue and the latter the absolute amount per kernel. In figure 4, values for free auxin are plotted on a content basis. The following points may be noted from these graphs:

(1) During development of the kernels, the peak auxin precursor and free auxin content is generally reached in the dough stage. At this point, all the corn samples with sugary endosperm contained from thirty to fifty million TDC per gram dry weight of total auxin (equivalent to 0.3 to 0.5 mg. of indoleacetic acid per gram of tissue), while samples with starchy endosperm contained fifteen to thirty million. In two instances (inbred WF, not reported here, and hybrid 487×479 , table 4), a total auxin yield of over eighty-four million TDC per gram dry weight was obtained. These values represent, with one possible exception (Linsner, 1940), the highest concentrations of total auxin and auxin precursor known to occur in plant tissues.

(2) There appears to be no fixed relationship between the absolute amounts of auxin precursor and free auxin accumulated in the kernels, except that the precursor always constitutes the major portion of the total obtainable at any time. In general, the proportion of free auxin is greater in the early than in the late stages of development. The curves for both the precursor and free auxin yields are of approximately the same shape throughout ontogeny, and the respective yields are of very nearly the same magnitude for a given endosperm type.

(3) It was pointed out that in the variety Country Gentleman, changes in total auxin concentration and dry matter content were closely associated with one another. In the inbreds and hybrids, both dry matter and total auxin concentration increase up to peak yields of the latter, but not always in constant proportion; nor are increases in free auxin content always proportionately related to changes in dry weight. From the auxin peak to maturity, the actual content of auxin per kernel decreases while dry matter continues to be accumulated.

To determine whether drying in itself was causal in decreasing the yield obtainable at dormancy, kernels of three different lines were air dried at their peak of total auxin concentration; re-assays were made after three months. In no instance was the loss of auxin precursor greater than 25 per cent, and the free auxin values were slightly higher than the original assays. Inasmuch as kernels allowed to mature normally lose about 80 per cent of their auxin, on the average, it appears that in addition to the drying of the kernels, other factors must be responsible for the markedly decreased auxin yields obtainable at maturity.

(4) In no instance do the auxin yields of the hybrids significantly exceed those of the inbreds, even though the hybrids show heterosis (table 3). This may be due to the material studied: the hybrid kernels tested were those growing on F_1 plants, and they, therefore, represented the F_2 generation. However, the F_2 kernels were produced on vigorous F_1 plants, and, if the vigor of a parent were accompanied by increased auxin production, one would think that the hybrid kernels might reflect this vigor in accumulating a greater auxin content. Preliminary results obtained with kernels of the F_1 generation

TABLE 3. *Data on vegetative and yield vigor of inbred and hybrid corn.*

Pedigree	Vegetative growth	Yield	
		Ave. ears per stalk	Ave. yield of dry shelled grain in bushels per acre
677	65% of hybrid	1.0	52
C-14	65% of hybrid	1.0	29
677 × C-14 ^a	1.0	105
Ave. number of kernels per ear			
14	50% of hybrid	1.5	284
5	90% of hybrid	1.5	358
14 × 5	1.0	700
75	50% of hybrid	2.0	205
77	75% of hybrid	1.5	256
75 × 77 ^b	2.5	600

^a Dr. D. F. Jones, of the Connecticut Agricultural Experiment Station, writes regarding 677 × C-14: "We think this is one of our most vigorous hybrids, when considered for its early production of grain."

^b Mr. E. B. Clark of the Associated Seed Growers, Milford, Conn., writes: "In the 75 × 77 hybrid we probably get a higher number of ears per plant, on the average, than with any other hybrid now in commercial production."

(presented in table 4), also failed to show any regular increases in auxin yields over the better of the parents.

If the auxin which accumulates in the kernels is calculated on a *per plant* basis, the hybrid considerably excels either parent in the case of 75 and 77 (fig. 5). This is attributable entirely to the greater number of kernels per ear and more ears per plant in the hybrid 75 × 77. The hybrids 677 × C-14 and 14 × 5 (fig. 5) do not give a higher auxin yield per plant than the better of the parents, even though

they exhibit greater vegetative vigor (table 3). Thus the evidence indicates that the vegetative vigor of the plant is not reflected in the amount of auxin accumulated in the kernels it bears. Where yield vigor is reflected in greater auxin content per plant, the auxin concentration per unit weight of kernels is no greater than that in kernels produced by less vigorous plants.

AUXIN CONTENT OF KERNELS FROM RECIPROCAL CROSSES.—Since vegetative vigor was found not to be reflected in higher auxin content of F₂ kernels

TABLE 4. *Auxin concentration in corn inbred and hybrid kernels at the late milk stage and at dormancy. All lines were pollinated August 3, 1941, and the late milk stage auxin assays were made on samples picked seventeen days after pollination. The dormant samples were harvested on October 7, except for (468) and (468 × 479), which were harvested on September 24. The reciprocal crosses included in this table are reported to have the same hybrid vigor.*

Pedigree	Kernel characteristics	Late milk stage				Dormant stage
		Yield in millions of TDC or tens of micrograms of indole-acetic acid per gm. dry weight		Dry wt. per kernel in mgs.	Per cent dry matter	Yield of total auxin in millions of TDC/gm. dry wt.
		Auxin precursor	Free auxin			
468	Yellow dent, medium sized kernels	44	4.1	18	17	0
468 × 479	48	6.7	20	18	2.8
479 × 468	17	1.3	49	19	0.8
479	White semi-dent, large kernels	33	3.0	42	19	3.8
479 × 487	19	1.6	50	21	1.2
487 × 479	80	4.2	22	23	2.3
487	White semi-dent, small kernels	48	2.8	20	20	1.1
487 × 485	37	2.7	15	17	0.3
485 × 487	7.0	1.5	35	22	0.5
485	Yellow dent, medium sized kernels	14	1.0	28	21	0.3

(growing on F_1 plants), it was thought worthwhile to explore the situation in F_1 kernels (growing on p_1 plants). For this purpose immature and mature kernels from reciprocal crosses and parental lines were supplied by John Shafer, Jr., of Cornell Uni-

versity. The data are presented in table 4, and the following points may be noted:

(1) As regards total auxin concentration, the high values obtained at the milk stage are comparable with the peak yields of other inbreds and hybrids (fig. 2 and 3). However, the yields at dormancy are in general lower than most of those encountered in our assays of dormant maize.

(2) Free auxin and auxin precursor concentrations in hybrid kernels are not regularly greater than those of the inbreds, even though the hybrid plants produced from these kernels all exceeded the inbreds in vegetative vigor. In one instance, however, the free auxin concentration of a hybrid (468×479) clearly exceeds both inbred parents, and in another instance (487×479) the auxin precursor concentration is about double that of the high parent. Thus these results are in accord with those shown in figures 2 and 3, and indicate again that there is no clear-cut relationship between vegetative vigor of hybrids and the amount of auxin which the kernels store.

(3) In every instance in table 4, the hybrids follow the maternal parent in auxin precursor concentration at the late milk stage, but at the dormant stage they follow the paternal parent (with one exception). However, from the dry weights it may be seen that the kernels of some lines had developed more rapidly than others by the milk stage, and in all cases the heavier kernels were lower in total auxin concentration. Therefore, the mere accumulation of dry matter may be of as much as, or more significance than, inheritance in determining the concentration of auxin in the kernel. Furthermore, the auxin concentrations vary greatly in hybrid kernels from reciprocal crosses, even though the F_1 plants which later came from such kernels are reported to have the same degree of vegetative vigor. The evidence for genetic control of auxin content, although suggestive, is entirely inadequate to establish any general trends. It should be emphasized again that these experiments were designed to discover any relationship between vegetative vigor and auxin content of kernels, rather than between heredity and auxin.

AUXIN CONTENT AND POLYPLOIDY IN CORN.—Polyploidy is frequently associated with increased size of plants or certain plant organs, and it is, therefore, of interest to know whether polyploidy is in any way reflected in the amount of auxin accumulated in kernels. A preliminary investigation of this problem was made possible through the courtesy of L. F. Randolph of Cornell University, who furnished immature kernels from two series of diploid and tetraploid corn at three stages of development. The results of this study are given in table 5. It may be noted that in both diploid series, auxin precursor concentration decreases with increase in weight of kernels; this observation does not hold for the tetraploids. On a per kernel basis, precursor content remains approximately constant in both diploid series, but increases with increasing kernel weight in the tetraploids. It might appear that the diploid kernels have higher total auxin concentration than the tetraploids, but here again, as in the case of the Cornell hybrids and inbreds, high total auxin concentration

Fig. 5. Total auxin (auxin precursor plus free auxin) per plant, based on average kernel number per ear, and average number of ears per plant. Above, data on kernel and ear number are given in graph. Below, (14) averages one and one-half ears per plant and 284 kernels per ear; (5) averages one and one-half ears per plant and 358 kernels per ear; (14 \times 5) averages one ear per plant and 700 kernels per ear.

versity. The data are presented in table 4, and the following points may be noted:

(1) As regards total auxin concentration, the high values obtained at the milk stage are comparable

TABLE 5. *Auxin yields in immature kernels from polyploid corn plants. All kernels possess a flinty endosperm.*

Pedigree	Stage of development ^a	Dry weight per kernel in mgs.	Per cent dry weight	Yield in millions of T D C or tens of micrograms of indoleacetic acid			
				Per gm. dry wt.		Per kernel	
				Auxin precursor	Free auxin	Auxin precursor	Free auxin
65-2N	a	9	16	50	3.2	0.45	0.03

	c	76	30	24	1.7	1.9	0.13

^a a, b, c represent successively older stages in development of the corn. An approximate idea of the ages of these kernels may be had by comparing the per cent dry weight values with similar figures given in table 1; in general, the stages ranged from blister to dough. It should be noted that no dormant (mature) kernels were assayed.

is associated with low kernel weight. The above exploratory experiments show no sufficiently definite relationship between polyploidy and auxin accumulation in immature kernels to justify any general conclusions. Further work must be done.

DISCUSSION.—The primary object of the investigation was to determine the changes in the amount of auxin stored in corn kernels as they developed from the time of pollination to maturity. All the varieties studied were characterized by a rapid rise in auxin content for about three weeks (milk-dough stage), followed by a marked decrease observed at the mature (dormant) stage. This sequence of rise and fall of auxin extractable from a cereal grain during ontogeny is very similar to the one reported by Hatcher and Gregory (1941) for winter rye. These authors pointed out that the rapid decrease in auxin after the peak is apparently closely related to desiccation, whereas in the present study, at least 50 to 75 per cent of the decrease was found not to be due to mere drying of kernels.

It is interesting to note that Laibach and Meyer (1935), using alcohol extraction and lanolin paste assays, also reported higher auxin yields from corn kernels in the milk stage than from either very young or mature kernels.

It has been pointed out in this study that kernels with sugary endosperm possess more auxin than those with starchy endosperm. This agrees with results of a previous study on a number of different endosperm types assayed in the dormant stage (Avery, Berger and Shalucha, 1942).

The second object of the investigation was to determine whether marked differences in vegetative vigor of plants are reflected in equally marked differences in the auxin content of the kernels they bear. The problem was, therefore, to determine whether or not the amount of auxin stored in the

kernels is related to the vigor of the parent plant. The data obtained indicate that it is not. It is realized, however, that to establish such a negative relationship beyond question requires further experiments. These are under way.

While the vegetative vigor of corn plants does not appear to be reflected in the auxin content of the kernels, it might of course be reflected in the auxin content of the vegetative tissue. This problem cannot yet be investigated because of the lack of adequate methods for extraction of auxin from green tissues.

SUMMARY

Maize kernels were harvested at intervals during their ontogeny from the varieties Country Gentlemen, Golden Cross Bantam, and a number of pedigree inbreds and hybrids; also from polyploid plants. Free and precursor auxin were extracted by a method involving alkaline hydrolysis, and the extracts were assayed by the *Avena* technique.

At the time of pollination the total auxin present in corn kernels is extremely small, but immediately after pollination the auxin content increases very sharply; a peak is reached in from one to three weeks, at which time the kernels contain the equivalent of 0.3 to 0.5 mg. indoleacetic acid per gram dry weight. From the peak to the dormant stage, there is a marked drop in auxin content which is characteristic of all the varieties studied.

No relationship was apparent between vegetative vigor of hybrids and the amount of auxin stored in the kernels produced by them.

No fixed relationship exists between the amounts of auxin precursor and free auxin, except that the precursor always constitutes the major portion of the total obtainable at any time.

Corn kernels with sugary endosperm are consist-

ently higher in total auxin than those with starchy endosperm.

Exploratory experiments with immature kernels of diploid and tetraploid corn also failed to reveal

any evidence of a relationship between polyploidy and the amount of auxin stored in kernels.

AN ACCOUNT OF THE SPECIES OF POLYSIPHONIA ON THE PACIFIC COAST OF NORTH AMERICA. I. OLIGOSIPHONIA¹

George J. Hollenberg

THE NAME *Polysiphonia* was first proposed by Greville (1824). *Hutchinsia* had been previously proposed for this group of plants by C. A. Agardh (1817), but proved inadmissible because of prior application of this name by Robert Brown to a group of cruciferous plants. At least fourteen other names have been employed at one time or another to designate this group, as listed by De Toni (1903). When first proposed, *Polysiphonia* included practically all of the evidently segmented plants now placed in the Rhodomelaceae. As finally delimited by Falkenberg (1901), *Polysiphonia* includes those radially symmetrical members of the Rhodomelaceae in which (1) at least the ultimate branches are evidently polysiphonous; (2) most of the branches arise exogenously by a more or less diagonal division of subapical cells before these have cut off pericentral cells; (3) all branches are essentially similar and indeterminate; and (4) only one tetrasporangium is borne normally in each segment. Erect branches arise mostly as assurgent extensions of prostrate branches or exogenously, but they may also arise endogenously from the central cells after the formation of pericentral cells.

Endogenous branches in *Polysiphonia* and closely related genera may usually be distinguished from exogenous branches, not only by their manner of origin, but also by the nature of the basal segment of the branch at the point of insertion. In exogenous branches there is usually a reduced number of pericentral cells in the basal segment. This is rarely if ever characteristic of endogenous branches. Furthermore, basal segments of exogenous branches are usually considerably shorter than corresponding segments in the parent branch and also considerably

shorter than more distant segments of the same branch.

Falkenberg (1901, p. 55) describes two types of endogenous origin of branches in the Rhodomelaceae. Normal endogenous branches arise at certain definite positions and in regular sequence in relation to the shoot apex. Adventitious branches arise endogenously at almost any position and do not bear a regular sequence relationship to the origin of other branches. In *Polysiphonia* all branches are adventitious since they do not arise in constant positions in regular sequence with respect to the segments. Although for the most part the branches are not endogenous, in several specimens of *P. hemisphaerica* Aresch. from the Baltic, which were examined, all branches seemed to be endogenous.

It seems also desirable to distinguish two types of exogenous branch. These may be designated as normally exogenous branches, which arise directly from branch primordia cut off from the subapical cells, and cicatrigenous branches, which arise from scar-cells. The scar-cells are persistent basal cells of trichoblasts, commonly left when the trichoblasts or hairs are shed. Since in *Polysiphonia* all trichoblasts arise exogenously, all cicatrigenous branches are indirectly exogenous. In *Polysiphonia* most of the so-called accessory branches are cicatrigenous, but the term accessory seems to be used somewhat loosely in this connection.

Falkenberg distinguishes two morphological or developmental types of branch in the Rhodomelaceae. Determinate branches, which do not ordinarily give rise to further branches, he designates as "Kurztriebe," whereas indeterminate branches of potentially unlimited growth are designated as "Langtriebe." In *Polysiphonia* all branches are at least

¹ Received for publication April 13, 1942.

theoretically indeterminate, although in certain species, and especially in certain varieties of *P. pacifica* of this paper, the ultimate branchlets are commonly more or less determinate.

As has been shown by Falkenberg (1901) and other investigators, the number of pericentral cells is usually quite constant if there are only four, but the number becomes in general more variable as the number of pericentral cells is increased. Tetrasporic branches usually appear to have one or two more pericentral cells than have the vegetative branches of the same plant, due to the formation of two cover cells by division of the fruiting pericentral cell.

With respect to the sequence of origin of pericentral cells in *Polysiphonia*, reference may be made to the work of Falkenberg (1901) and Rosenberg (1933). No data in regard to this question are available in the case of the species treated in this paper.

Trichoblasts or hairs are present in most species of *Polysiphonia*. In a few species trichoblasts are entirely wanting. In other species they are exceedingly rare or seasonal in their occurrence, or occur only in connection with sexual reproductive structures. As pointed out by Falkenberg (1901), trichoblasts always arise exogenously. In most cases they are soon deciduous. The basal cell is usually very short and persists as an inconspicuous scar-cell at the node between the pericentral cells. In certain species some of the trichoblasts, especially those in whose axils branches arise, do not leave scar-cells. Under circumstances as yet poorly understood, trichoblast primordia may remain undeveloped and form persistent scar-cells directly. As has been already pointed out, the scar-cells may sometimes give rise to cicatrigenous branches, but most of them do not.

Trichoblasts usually arise in very definite positions, which have been shown by Falkenberg (1901) to be of very great taxonomic importance. There seem to be no known cases in which more than one trichoblast has arisen on a given segment. Most commonly a single segment intervenes between successive trichoblasts, but in some species two or more segments occur between successive trichoblasts. The trichoblasts are usually arranged in a spiral line running in a counter-clockwise direction toward the tip of the branch, when the branch is viewed from the apex. Accordingly, Rosenberg (1933) and other investigators, who have studied the origin of branches and trichoblasts in *Polysiphonia*, speak of the trichoblasts as usually spiralling to the left. Plants are rarely found in which the direction of the spiral is reversed. The divergence of the trichoblasts in the spiral is relatively constant and usually bears some relation to the number of pericentral cells.

In most of the species of *Polysiphonia* found on the Pacific coast of North America the position of the trichoblasts is a very constant feature, but in at least one local species they are very irregularly placed, as they are in a number of European species. Even in such cases, however, there is often a distinct

tendency for the trichoblasts to be arranged in definite positions.

Exogenous branches, arising subapically, almost invariably appear in positions comparable to those in which the trichoblasts arise and in the same spiral line, so that trichoblasts and branches are homologous structures with respect to origin. In some cases the entire primordium becomes the branch, but in other species the primordium divides and one fork, usually the outer one, develops into a trichoblast and the other one develops into the branch. Hence various investigators speak of branches as originating in connection with trichoblasts or not in connection with trichoblasts (replacing trichoblasts). Trichoblasts in whose axils branches arise are sometimes spoken of as "leaves."

In certain species of *Polysiphonia* the pericentral cells are more or less obscured by the development of an outer layer of cortical cells. The cortical filaments arise from small cells cut off in most cases from the corners of the pericentral cells.

As has been shown by Falkenberg (1901) and confirmed by later studies, the vegetative features, briefly discussed in the preceding paragraphs, are much more important taxonomically than are the reproductive features. The latter exhibit for the most part a monotonous uniformity. Accordingly an extended discussion of the reproductive structures of *Polysiphonia* is neither desirable nor necessary for the present purpose. Such differences as do occur will be mentioned in connection with the different species in so far as reproductive structures are known.

A great deal of synonymy has accumulated in the genus *Polysiphonia*, especially in the tetrasiphonous members of the genus. Much of this synonymy could probably have been avoided if more attention had been given to critical structural features, which have for the most part been pointed out by Falkenberg (1901). Especially important are the positions of trichoblasts and scar-cells; origin of branches, whether endogenous or exogenous, whether entirely replacing trichoblasts or arising in connection with them; and the nature of the antheridial branches and their relation to trichoblasts. Another feature of considerable taxonomic significance which needs more attention is the nature and origin of attachment organs. A monographic treatment of the genus is greatly needed, but can hardly be undertaken in the present state of international relations.

Twenty-one species of *Polysiphonia* are known to the writer from the Pacific coast of North America. One of these, *P. Brodiaei* Grev., is practically indistinguishable from the European plant of that name and may prove to be an introduced species. *P. pacifica* n. sp. is closely similar to *P. urceolata* (Lightf.) Grev. from Europe and the Atlantic coast of North America. *P. curta* Montague and *P. paniculata* Montagne and possibly *P. pacifica* are found also on the Pacific coast of South America. Although not at present evident, it seems probable that further study may show some definite affinities between the

species on the two sides of the Pacific basin. Within the range of the study, *P. paniculata* and varieties of a species which has been heretofore designated as *P. sancti-petri* Collins, as well as varieties of *P. pacifica*, are found along the entire Pacific coast of North America. *P. Macounii* n. sp. is known only from the region of Vancouver Island, and *P. pungens* n. sp. only from Vancouver Island to the southern Alaskan coast. *P. Brodiaei* and *P. Snyderae* Kylin occur from Washington to southern California, and *P. flaccidissima* n. sp. occurs from central to southern California. The remaining thirteen species are known only south of Point Conception on the coast of California. Two species are so far known only from the Gulf of California.

Along the California coast there seems to be no marked seasonal fluctuation in the occurrence of the various species of *Polysiphonia*, except in the case of *P. flaccidissima*, which seems to occur in abundance in characteristic locations only during the fall and winter months. There is likewise little or no evidence of seasonal variation along the coast of Oregon and Washington, but insufficient collections are available for conclusive statements. Collections from Alaska are of course very inadequate.

During the progress of the study all specimens from the region were examined which are to be found in the following herbaria (designated in the treatment of species by the accompanying symbols): University of California (C); Farlow Herbarium (F); Marshall Field Museum of Natural History (Fi); Hopkins Marine Station (Hop.); New York Botanical Garden (N.Y.); University of Washington (W); and the herbarium of the writer (H). In addition the writer has been privileged to examine specimens collected by Dr. Francis Drouet and Mr. Donald Richards along the coast of Sonora, Mexico, in 1939, by Mr. E. Yale Dawson in the Gulf of California in 1940, and by Dr. W. R. Taylor off the west coast of Mexico during the Hancock expedition of 1934. The writer is grateful for the opportunity of examining material from all of these sources, and is especially indebted to the late Dr. N. L. Gardner of the University of California whose numerous collections along the entire Pacific coast of North America have so greatly facilitated this study. Of the many specimens examined only a few representative specimens other than the types will, in the case of most species, be cited. Specimens in the above mentioned herbaria have been fully annotated for the most part and citation in this paper seems unnecessary.

The tetrasiphonous species will be treated in part I of this paper, and the species with five or more pericentral cells will be taken up in part II to appear at a later date.

Key to the species of Polysiphonia on the Pacific Coast of North America

1. Plants with 4 pericentral cells..... 2
1. Plants with more than 4 pericentral cells (Part II of this paper)12
2. Trichoblasts and scar-cells wanting or very rare; tetrasporangia in straight series..... 3
2. Trichoblasts or scar-cells frequent to abundant.. 4
3. Ultimate branchlets sharply pointed and more or less determinate.....*P. pungens* n. sp.
3. Ultimate branchlets not sharply pointed, although frequently more or less determinate.
P. pacifica n. sp.
4. Trichoblasts and scar-cells infrequent and irregularly inserted.....*P. sonorensis* n. sp.
4. Trichoblasts and scar-cells frequent and in regular positions 5
5. Trichoblasts and branches alternating in spiral succession 2-3 segments apart and with $\frac{1}{4}$ divergence.
P. decussata n. sp.
5. A trichoblast, scar-cell, or a branch occurring on every segment 6
6. Plants with longitudinal cortical filaments on older parts.....*P. Macounii* n. sp.
6. Plants without cortical filaments..... 7
7. Plants minute tufted epiphytes mostly under 1 cm. high, with endophytic rhizoids composed of two cells.....*P. minutissima* n. sp.
7. Plants larger, rhizoids unicellular..... 8
8. Segments in main axes rarely longer than broad.. 9
8. Segments in main axes commonly longer than broad10
9. Main axes very prominent and straight; plants tufted, mostly epiphytic.....*P. acuminata* Gard.
9. Main axes less prominent, plants forming low mats on rocks.....*P. simplex* n. sp.
10. Branching dichotomous throughout; plants with discoid attachment.....*P. Masonii* S. & G.
10. Branching not dichotomous throughout; attachment usually not discoid.....11
11. One fork of branch primordia forming a trichoblast, branches arising accordingly in the axils of trichoblasts.....*P. flaccidissima* n. sp.
11. Branch primordia not forming trichoblasts but entirely replacing them.....*P. Snyderae* Kylin

POLYSIPHONIA *pungens* sp. nov. (fig. 1, 10).—Plantae 10–15 cm. altae, profuse ramosae, cum ramis fere laxis praecipue deorsum; axibus principibus 180–260 μ crassis, cum segmentis 8–15 diametros longis; subultimis ramis virgatis et in segmentis 2–4 ramula breviora et recta et determinata et acute pungentia undique ferentibus; ramulis apicem ramorum parce aut non excedentibus; cellulis pericentralibus 4, omnino ecorticatis; trichoblastis et cicatricellulis deficientibus; tetrasporangiis in seriebus rectis in ramulis ultimis; cystocarpis et ramis antheridialibus ignotis; colore rubro aut fusco-rubro.

Plants 10–15 cm. high, profusely branched, with branching mostly lax, especially below; main axes 180–260 μ in diameter, composed of segments 8–15 diameters long; subultimate branches virgate, bearing at intervals of 2–4 segments relatively short straight determinate and sharply pointed branchlets on all sides; branchlets not at all or scarcely exceeding the branch tips; pericentral cells 4, without cortication; trichoblasts and scar-cells wanting; tetrasporangia in straight series in the ultimate branchlets; cystocarps and antheridia unknown; plants red or brownish purple, known only from the vicinity of Vancouver Island, British Columbia and from Alaska.

Fig. 1-9. All drawings were made with the aid of a camera lucida.—Fig. 1. Portion of a branch of *P. pungens* n. sp. $\times 85$.—Fig. 2. Tetrasporic branch of *P. pacifica* n. sp. $\times 80$.—Fig. 3. Tip of a branch of *P. pacifica* n. sp. $\times 360$.—Fig. 4. Branch tip of *P. pacifica* var. *disticha* n. var. $\times 85$.—Fig. 5. Branch tip of *P. sonorensis* n. sp. $\times 70$.—Fig. 6. Branch tip of *P. decussata* n. sp. $\times 360$.—Fig. 7. Portion of a larger branch of *P. Macounii* n. sp. $\times 17$.—Fig. 8. Branch tip of *P. flaccidissima* n. sp. $\times 325$.—Fig. 9. Branch tip of *P. Snyderae* Kylin. $\times 360$.

Type no. 314925 in the herbarium of the University of California, collected by R. B. Wylie on Valenar Rock, Gravina Island, lat. $55^{\circ} 26' N.$, Alaska, May, 1913. Several additional specimens from British Columbia were collected by John Macoun, of the Geological Survey of Canada about 1909, or perhaps a few years previous to this time: Macoun 34, without date or locality (F); Macoun 93, Vancouver Is.,

without date (C); Macoun 136, Qualicum, Vancouver Is., without date (N.Y.).

This species is very close to *P. pacifica* of this paper, especially to those varieties with determinate branchlets. It differs in the virgate ultimate branches and the sharply pointed branchlets which they bear. The color is usually more red and not dark brownish or black as is common on *P. pacifica* var. *determinata*.

POLYSIPHONIA pacifica sp. nov. (fig. 2, 3, 12, 13). —Plantae medio-rubrae aut fusco-rubrae vel parce nigrae et molles aut firmae, cum filamentis repentibus inconspicuis, per rhizoidia unicellularia in intervallis irregularibus affixae, unum solum per segmentum, ex centro inferiorum cellularum pericentralium ut ex-crescentia orta, a quibus muris transversis non abscissa sunt; ramis erectis fere endogene ortis, (2) 10–20–(25) cm. altis, laxe ramosis praecipue infra, fere cum nudis regionibus longioribus; ramis alternantibus, interdum aliquanto distichis, cum axibus primis distinctis aut indistinctis et 60–200–(300) μ crassis; ramis multorum ordinum; ramulis fere apicem crescentem haud excedentibus; fere cum 3–5 segmentis inter ramos succedentes; cellulis pericentralibus 4, omnino ecorticatis; segmentis ramorum primorum fere 6–10 diametros longis, multo brevioribus in ramulis ultimis, qui fere apice attenuati sunt; trichoblastis et cicatricellulis rarissimis; tetrasporangiis 60–70–(100) μ crassis, in seriebus longis et rectis in ramulis ultimis, tripartite divis; cystocarpis ovoido-globosis, leviter vel manifeste urceolatis, brevius pedicellatis, 200–500 μ crassis; cylindratis ramis antheridialibus cum breve apice sterile unius aut plurium cellularum, ab toto ramo fructifero ortis; plantae fere saxis adhaerentes.

Plants medium to dark red or nearly black, adhering well or poorly to paper, with inconspicuous creeping filaments attached by unicellular rhizoids arising at irregular intervals, never more than one per segment, as outgrowths from the center of the lower pericentral cells, from which they are not cut off by cross walls; erect branches arising mostly endogenously, 10–20–(25) cm. high, mostly laxly branched, especially below, with relatively long naked regions; branching alternate, sometimes somewhat distichous, with main axes distinct or indistinct, 100–200–(300) μ in diam.; branches of many orders, typically not exceeding the growing tip, with (2)–4–5—many segments between successive branches; pericentral cells 4 in vegetative branches, totally ecorticate, the segments in the main branches (4)–6–10–(20) diam. long, well separated by clear septa and much shorter in the ultimate branchlets, which are commonly considerably attenuate at the tip but not pungent; trichoblasts and scar-cells exceedingly rare; tetrasporangia 60–70–(100) μ diam., in long straight series in the ultimate branchlets, tripartitely divided; cystocarps slightly to conspicuously urceolate, briefly pedicellate, 200–500–(675) μ in diam.; antheridial branches cylindrical, with a short sterile tip of one to several cells, formed from the entire fruiting branch; plants growing on rocks, pilings, etc., in the lower littoral and sublittoral zone from Alaska to Lower California.

A specimen (fig. 12) in the herbarium of the New York Botanical Garden has been selected as the type. It was collected by Dr. C. L. Anderson at Santa Cruz but bears no date. It is tetrasporic. A more delicate representative of the species is shown in figure 13.

of a portion of a male plant from the type material of *P. minutissima* n. sp. $\times 15$, showing the basal tuft of rhizoids in the lower right hand corner.

This plant was collected by N. L. Gardner, 2750, from stones and logs, at Empire, Coos Bay, Oregon. *P. pacifica* is a very variable species, as is *P. urceolata* (Lightf.) Grev., to which it is closely related. The latter plant is common in Europe and along the Atlantic coast of North America. In both plants the antheridial branch arises from the entire trichoblast primordium. The sterile tip is generally much shorter, however, in the Pacific coast plant. In both plants the rhizoids arise as extensions from the middle of the lower pericentral cells and are not cut off by cross walls from the pericentral cells. The Pacific Coast plant is in general somewhat more robust and a much more variable plant. Furthermore, trichoblasts and scar-cells are much more rare in the case of the Pacific Coast plant. These structures are reputed to be rare in the case of *P. urceolata*, but the writer has been able to find either trichoblasts or scar-cells in nearly every specimen of *P. urceolata* which was examined from the Atlantic coast of North America and in many of those from Europe. In over a hundred specimens of *P. pacifica* which were examined, representing collections during all seasons of the year, only one instance of either trichoblasts or scar-cells was observed except for occasional trichoblasts on cystocarps and scar-cells left by deciduous antheridial branches.

Among the specimens of *Polysiphonia* from Peru, which M. A. Howe (1914) identified as *P. abscissa* Hook. and Harv., several seem identical with typical specimens of *P. pacifica*, but as Howe states, several entities are probably represented in the Peruvian material under this name, and the writer has been unable to obtain authentic material of *P. abscissa* from the Cape Horn region from which the type came.

Key to the varieties of *P. pacifica*

1. Plants small and delicate, mostly under 4 cm. high.
P. pacifica var. *delicatula* n. var.
1. Plants larger and more robust, commonly 10–25 cm. high 2
2. Ultimate branchlets relatively short, rigid and more or less determinate..... 3
2. Ultimate branchlets indeterminate..... 5
3. Ultimate branchlets more or less distichous, main axes usually covered with branchlets throughout..... *P. pacifica* var. *disticha* n. var.
3. Ultimate branchlets not noticeably distichous, main axes usually with long naked portions below 4
4. Branching usually dense, main axes macroscopically indistinct above and commonly exceeded by the uppermost branchlets.
P. pacifica var. *determinata* n. var.
4. Branching lax to very lax, main axes distinct to the tips, which are usually not exceeded by the upper branchlets..... *P. pacifica* var. *gracilis* n. var.
5. Branches mostly delicate and soft, abundantly branched; color red..... *P. pacifica* n. sp.
5. Branches coarse to very coarse, up to 300 μ in diameter, distant; color usually very dark.

P. pacifica var. *distans* n. var.

P. pacifica var. **delicatula** var. nov.—Plantae rubrae, 0.5–2.0 cm. altae; axibus principibus 60–110 μ crassis, cum segmentis 1.5–2–(3) diametros longis; ramis omnibus indeterminatis, cum apicibus brevibus et fere obtusis; apicibus frequenter aliquanto forcipatis; trichoblastis raris; tetrasporangiis 50–60 μ crassis in seriebus rectis; cystocarpis aperte sine trichoblastis; ramis antheridialibus tenuibus, 140–200 \times 30–40 μ crassis, in pediculis brevissimis, cicatricellulas persistentas relinquentibus; plantae ad saxa et sublicas, fere in aqua profunda aut placida, affixae.

Plants red, 0.5–2.0 cm. high, rarely higher, main branches 60–110 μ diam., of segments 1.5–2–(3) diameters long; branches all indeterminate short and mostly blunt; branch apices often somewhat forcipate; trichoblasts wanting or exceedingly rare; tetrasporangia 50–60 μ in diam., in straight series; cystocarps seemingly without hairs; antheridial branches slender, 140–200 \times 30–40 μ , on very short pedicels, leaving persistent scar-cells when shed; plants occurring from central California to the Gulf of California, Mexico, on pilings and rocks in deep or sheltered water.

Type: Hollenberg 2888, collected from low tide level on pilings of the municipal wharf at Monterey, California, July 20, 1939, male and cystocarpic (H.). This plant has more rigid and more forcipate tips than have plants from the lagoons of southern California and from the Gulf of California. The scar-cells left by deciduous antheridial branches indicate that the antheridial branches are homologous with trichoblasts and not with branches of the thallus as Falkenberg (1901) concluded in the case of the similar antheridial branches of *P. urceolata*.

P. pacifica var. **disticha** var. nov. (fig. 4, 17).—Plantae 3–7 cm. altae, cum structura et ramis fructiferentibus ut in specie, sed plantis fere parvioribus, cum ultimis ramulis determinatis, primum incurvatis, demum rectis aut recurvatis, cum apicibus acutis, spiraliter alterne aut vulgo in alternis geminis, in intervallis 2–3 segmentorum, per totam longitudinem omnium ramorum ortis, vulgo partim distichis aut aperte distichis fere propter axem modice torsum.

Plants 3–7 cm. high, with chief structural features and reproduction as in the species, but plants mostly smaller with ultimate branchlets determinate, at first incurved, and finally straight or strongly incurved, with acute tips, spirally arranged in an alternate manner or commonly in alternating pairs every 2–3 segments throughout the length of all branches, commonly partly distichous or apparently distichous as a result largely of twisting of the axis; plants occurring mostly in the upper littoral zone in exposed places, central California to Vancouver Island, British Columbia, and probably extending northward.

Type: no. 276091 (fig. 17) in the herbarium of the University of California, collected by N. L. Gardner, 3888a, on the ocean side and three miles south of Cape Flattery, Washington, June, 1917. Other specimens examined include: N. L. Gardner 4405, from a stone wall above high tide level, "Fort Point," San

Francisco, California, Feb. 1919 (C., H.); and N. L. Gardner 3850, from the type locality, April, 1927 (C.). This variety has more or less determinate branchlets as in var. *determinata*, in which the branchlets are likewise somewhat distichous at times, but var. *disticha* is usually much smaller and its main axes are clothed with more or less determinate branchlets below as well as above.

P. pacifica var. **determinata** var. nov.—Plantae fere 10–15 cm. altae, deorsum laxae, cum axibus principibus 170–340 μ crassis, et segmentis deorsum 6–8 diametros longis, sursum brevioribus; ultimis ramulis crassioribus, aliquanto determinatis et plerumque cristas densas et aliquanto pencillatas formantibus, plerumque apicem crescentem aperte excedentibus, fere non distichis; trichoblastis solum in exemplis raris visis; tetrasporangiis et ramis antheridialibus ut in specie; cystocarpis magnis et aliquanto urceolatis; plantae fusco-rubrae.

Plants mostly 10–15 cm. high, lax below, with main axes 170–340 μ in diameter and segments 6–8 diameters long below, and shorter above: ultimate branchlets relatively coarse, more or less determinate and often forming more or less dense pencillate tufts, often extending well beyond the growing point of the branch, and mostly not distichous; trichoblasts wanting except for very rare instances; tetrasporangia and antheridial branches as in the species; cystocarps relatively large and more or less urceolate; plants dark brownish red to nearly black when dry, adhering only moderately well to paper from which they are readily loosened on moistening, occurring from central California to Alaska.

Type: N. L. Gardner 3827, on rocks, low littoral zone in cove beyond the first point south of Pebble Beach, Monterey County, California, May 1916 (C. 276272); Phyc. Bor. Amer. 1697, at least in part, John Macoun, Vancouver Is., British Columbia.

Many additional specimens of this common variety are to be found in the various herbaria mentioned. Similarities between this and the preceding variety have already been mentioned in connection with the discussion of that variety. In no. 3888 (C., H.) collected by N. L. Gardner from the upper littoral tide pools along the open coast 3 miles south of Cape Flattery, Washington, frequent forked hairs were present toward the branch tips, and occasional scar-cells were present. They were not in any constant positions, however, and the tetrasporangia were in straight series as in the species.

P. pacifica var. **gracilis** var. nov. (fig. 11).—Plantae obscure fusco-rubrae, 10–20 cm. altae, laxiores ramosae; ramis ordinum plurium, cum axibus principibus distinctioribus, vulgo deorsum nudis, sursum cum 1-multis subramulis; structura et tetrasporangiis ut in specie; cystocarpis et antheridiis ignotis.

Plants dull brownish red, 10–20 cm. high, very laxly branched in most cases; branches of several orders, with leading axes very distinct and commonly

naked below, above with slender lateral branchlets, which are more or less determinate and mostly simple or with 1-several short ramuli toward their tips; finer structural details and tetrasporangia as in the species, cystocarps and antheridia unknown; plants known only from the vicinity of San Juan and Orcas Islands along the coast of Washington.

Type: N. L. Gardner 2313, dredged in Deer Harbor, Orcas Island, Washington, July, 1910 (No. 273756 in the Univ. of Calif. herbarium). A single additional collection is from the same general locality, by J. S. Martin 33, extreme low littoral, exposed to swift currents, Twin Rock, 2 miles east of Friday Harbor, San Juan Island, Washington, Aug. 1940 (W.). This variety is distinguished by its slender laxly branched habit and determinate, mostly unbranched branchlets. There are many segments between successive branches in the lower parts, but mostly four between the ultimate or subultimate laterals. Segments in the main branches are many diameters long below and mostly 2 diameters long above. Lateral branchlets which in turn bear short ramuli usually have 20-30 segments between the base of the branchlet and the first ramulus.

P. pacifica var. *distans* var. nov. (fig. 16).—Plantae crassulae sed flexiles, fusco-rubrae, 10-18 cm. altae, cum axibus principibus ad 300 μ crassis et segmentis 2-4-(8) diametros longis; ramis distantibus praecipue deorsum, cristas pencillatas non formantibus; ramulis juvenibus saepe valide incurvatis; cystocarpis urceolatis, 550-675 μ crassis, cum labro ostioli crasso et fere quadralobato; tetrasporangiis in seriebus brevibus ad apicem ramulorum breviorum et ultimorum; plantis antheridialibus ignotis.

Plants coarse but limber, dark brownish-red, drying darker, 10-18 cm. high, with main axes up to 300 μ in diam., of segments 2-4-(8) diameters long; branching distant especially below; branches not forming pencillate tufts; young branchlets often strongly incurved; tetrasporangia in short series near the tips of short ultimate branchlets; cystocarps urceolate, 550-675 μ in diam., with thick mostly four-lobed ostiolar rim; antheridial plants unknown; plants adhering only moderately well to paper, occurring from British Columbia to central California.

Type: Hollenberg 2722, cystocarpic, afloat at the south end of Carmel Beach, Monterey County, California, June 22, 1939 (H.), (Isotype, Hop.). Three additional collections may be mentioned; Port Renfrew, British Columbia, Misses E. Butler and J. Polley 112, without date but probably about 1900, and distributed by W. A. Setchell as *P. senticulosa* Harv. (C.); Vancouver Island, B. C., without date, Robert Connell, tetrasporic (C.); Santa Cruz, C. L. Anderson without date, with some of the characteristics of *P. pacifica* var. *determinata* (N. Y.). The coarse laxly branched filaments, very large cystocarps, and tetrasporangia in short series seem the distinctive features of this variety.

POLYSIPHONIA sonorensis sp. nov. (fig. 5, 20).—Plantae 4-5 cm. altae ex ramis prostratis et repentibus; ramis prostratis 120-175 μ crassis, per rhizoidia unicellularia in intervallis irregularibus affixis; rhizoidiis uno solo per segmentum, ex centro inferiorum cellularum pericentralium excrecentibus, per muros transversos non abscissis; erectis ramis ex ramis prostratis fere endogene aut interdum exogene ortis, 70-100 μ crassis, cum segmentis fere 1.5-2 diametros longis, aliquanto dense ramosis, cum ramis lateralibus exogene fere in angulis acutis orientibus in intervallis irregularibus fere 10-20 segmentis separatis; ramis principibus indistinctis; ramulis ultimis tenuibus, 30-35 μ crassis, ad fundamentum modice attenuatis, ex segmentis fere unum diametrum longis aut brevioribus; cellulis pericentralibus 4, ecorticatis; trichoblastis tenuibus et numerosis ad 1 mm. longis, in intervallis irregularibus, cum 1-2 furcis, deciduis, frequenter cicatricellulas persistentes relinquentibus; ramis cum trichoblastis in origine non conjunctis; ramis fructiferentibus ignotis; plantis colore similibus lateri.

Plants forming dense tufts of a terra cotta color, 4-5 cm. high from prostrate creeping filaments; prostrate filaments 120-175 μ diam., attached by unicellular rhizoids which arise as outgrowths of the center of the pericentral cells, from which they are not cut off by cross walls; erect branches arising mostly endogenously or sometimes exogenously from the prostrate branches, 70-100 μ in diam., their segments mostly 1.5-2.0 diam. long; branching dense, the lateral branches arising exogenously at irregular intervals (4)-10-20 or more segments apart, mostly at an acute angle with the main axis, which is usually indistinct; ultimate branchlets slender, 30-35 μ in diam., slightly narrowed at the base, of segments mostly 1 diam. long or shorter; pericentral cells 4, not corticated; trichoblasts numerous, delicate, arising at irregular intervals, once or twice forked, to 1 mm. long, deciduous, often leaving inconspicuous scar-cells; branches not associated with trichoblasts in origin; reproduction unknown; plants adhering moderately well to paper on drying but readily removed, known only from the Gulf of California.

The type specimen is no. 3426a collected by Francis Drouet and Donald Richards afloat along the southeastern shore of the bay of Empalme, Sonora, Mexico, Dec. 23, 1939 (Fi.). The same investigators also collected this plant as no. 3144 (Fi.) from rocks between tide marks on the northwest shore of the harbor at Guaymas, Sonora, Mexico, on Dec. 4 of the same year.

In the nature and origin of the rhizoids, the pelucid nature of the transverse septa, and general structural details this plant closely resembles *P. pacifica*. It differs from the latter in the numerous irregularly occurring trichoblasts, which are exceedingly rare in *P. pacifica*; and also in having a greater number, and a more irregular number, of segments between successive branches. The frequent trichoblasts suggest a possible affinity with *P. urceolata* (Lightf.) Grev., but in the latter species the tricho-

blasts when present seem to be more regularly arranged in a spiral with one-fourth divergence according to Rosenvinge (1924) and other investigators. Furthermore, according to Falkenberg (1901) there is a more or less constant interval of 3-4 segments between successive branches in *P. urceolata*. Finally the terra cotta color of *P. sonorensis* is seemingly distinctive. From the imperfectly known *P. subtilissima* Montagne the present species differs in color, in the narrower angle of insertion of the branches, and in the manner of branching which does not seem at all dichotomous below in *P. sonorensis* as described for *P. subtilissima*. The Pacific coast plant also has more numerous trichoblasts than have specimens of *Polysiphonia* from the coast of Mississippi identified as *P. subtilissima* by W. R. Taylor.

POLYSIPHONIA decussata sp. nov. (fig. 6).—Plantae 1-2 cm. altae, assurgentes ex fundamento prostrato et repente, 150-180 μ crasso et cum segmentis fere circiter unum diametrum longis, per rhizoidia unicellularia 160 aut etiam 800 μ longa cum apicibus lobatis affixo; rhizoidiis in brevioribus intervallis ortis, fere unum per segmentum, ab fine proximale cellularum pericentralium a quibus muro transverso non abscissa sunt; ramis erectis 150-170 μ crassis, cum segmentis 0.5-1.0-(1.5) diametros longis; ramis plurium ordinum, exogenibus aut rare cicatrigenibus, fere alternante distichis in 4-6 segmenta; ramulis ultimis forte incurvatis, saepe apices ramorum excedentibus et superarcuantibus; cellulis pericentralibus 4, circum parvum cellulam centralem, omnino ecorticate; trichoblastis simplicibus aut semel aut bis furcatis, 200-360 longis, decussate alternantibus cum ramis ita dispositis ut rami cum trichoblastis aut cicatricellulis persistentibus laevam spiram quantum divergentum faciant; trichoblastis aut cicatricellulis distichis in ramulis ultimis, fere 2 segmenta separatis; cicatricellulis saepe ex trichoblastorum primordis orientibus; tetrasporangiis 35-60 μ crassis, in seriebus aliquanto continuis in ramulis ultimis, irregularibus sed apparenter in spiris non positis; cystocarpis ovoidis, aliquanto urceolatis, breve pedicellatis 250-320 x 300-430 μ crassis, in loco rami; ramis antheridialibus 30-40 x 100-150 μ , ramum primum trichoblasti constituentibus; plantae colore fusco-russeo, saxis adhaerentes.

Plants 1-2 cm. high, assurgent from a prostrate creeping base 150-180 μ in diam. and composed of segments mostly about 1 diameter long, attached by unicellular rhizoids up to 160 or even 800 μ long with lobed tips; rhizoids arising at short intervals, seldom more than one per segment, from the proximal end of the pericentral cells from which they are not cut off by a cross wall; erect branches 150-170 μ in diam., their segments 0.5-1.0-(1.5) diam. long; branches of several orders, exogenous or rarely cicatrigenous, arising in an alternately distichous manner every 4-6 segments; ultimate branchlets strongly incurved, often exceeding and overarching the branch tip; pericentral cells 4 around a small central cell, totally ecorticate; trichoblasts simple or

once or twice forked, 200-360 μ long, decussately alternate, with the branches so arranged that they, together with the trichoblasts or persistent scar-cells, form a left hand spiral with $\frac{1}{4}$ divergence, 2-3 segments intervening between a branch and the next higher or lower trichoblast in the spiral; trichoblasts and scar-cells distichous on the ultimate branchlets, mostly 2 segments apart; scar-cells often represented by undeveloped trichoblast primordia; tetrasporangia 35-60 μ in diam., in more or less continuous series in the ultimate branchlets, shifting in position but seemingly not in a regular spiral arrangement; cystocarps ovoid, somewhat urceolate, briefly pedicellate, measuring 250-320 x 300-430 μ , replacing a branch; when young surmounted by a slender forked hair; antheridial branches 30-40 x 100-150 μ , arising as a primary branch of a trichoblast; plants deep reddish brown, forming tufts or somewhat matted on rocks or intermingled with other matted algae.

Type: Hollenberg 2649, cystocarpic, tufted, on boulders, medium low tide level, near the mouth of Topango Canyon, Los Angeles County, California, June 4, 1939 (H.). Only two other collections have been made: at Fairview Point, Laguna Beach, Orange County, California, Hollenberg 1114, tetrasporic, Nov. 1935 (H.); and at Park Point, LaJolla, San Diego County, California, in the middle littoral zone on rocks, Hollenberg 2634a, male, May, 1939 (H.).

This diminutive plant seems very distinct from other Pacific coast species, especially in the arrangement of the branches and trichoblasts. Branch tips frequently have the aspect of a *Pterosiphonia*, but it is excluded from that genus because of the trichoblasts and the nondecurent insertion of the branches and shortened basal segments of branches. The arrangement of trichoblasts and branches is very similar to that of a series of plants from the Atlantic coast of both North and South America, which have been commonly identified as *Polysiphonia subtilissima* Montagne. However, the Atlantic coast plants are much larger, up to 12 cm. high and more irregularly branched. Several plants from the coast of Mississippi, which are considered by W. R. Taylor to be more definitely identified with the type of *P. subtilissima*, were found by the writer to have little if any regularity in the insertion of the branches. They are much more laxly branched than the Pacific coast plants and young branchlets are not at all incurved.

POLYSIPHONIA Macounii sp. nov. (fig. 7, 14).—Plantae 10-12 cm. altae ex ramis repentibus et dense implexis, per rhizoidia unicellularia et numerosa affixae; axibus principibus 500-600 μ crassis, cum segmentis deorsum 1-2 diametros longis et sursum brevioribus diametro; ramis aliquot vel multorum ordinum, fere exogenibus; ultimis ramulis numerosis et fere aliquanto determinatis, brevibus et calcari similibus et obtusis; cellulis pericentralibus 4, cum corticatis filamentis sparsis, in longitudinem juncturis cellularum pericentralium axis primi extensis; trichoblastis furcatis et brevibus, una per segmentum

spiram laevam quantum divergentem facientibus, mox deciduis, cicatricellulas persistentes relinquentibus; ramis a cicatricellulis frequenter ortis; ramis trichoblastorum vicem; ramis fructiferentibus ignotis.

Plants 10–12 cm. high from densely matted creeping branches attached by numerous unicellular rhizoids; main axes 500–600 μ in diam., their segments 1–2 diam. long below, and shorter than broad above; branches of several to many orders, mostly exogenous, the ultimate branchlets abundant, short obtuse and spur-like, and mostly more or less determinate; pericentral cells 4, with a number of cortical filaments extending longitudinally along the junctures of the pericentral cells in the main axes; trichoblasts short and forked, one on each segment, arranged in a left hand spiral with $\frac{1}{4}$ divergence, soon deciduous, leaving scar-cells from which accessory cicatrigenous branches may arise in considerable numbers; branches replacing trichoblasts; reproductive structures unknown; plants known only from the vicinity of Vancouver Island, British Columbia.

A series of specimens in the herbarium of the New York Botanical Garden is considered the type collection. These specimens are to be found in a packet labeled "*P. senticulosa*" from the Collins herbarium. Fragmentary notes on portions of the original wrapper indicate that this collection is no. 105, collected by John Macoun at Qualicum, Vancouver Island, British Columbia. No date is given, but John Macoun, who was naturalist on the Geological and Natural History Survey of Canada, probably collected this material about 1909 or shortly previous to this time. The only other known specimens were likewise collected by Macoun from the same general region; John Macoun no. 106, without date or locality (C.); Amphitrite Point, Barkley Sound, west coast of Vancouver Is., Macoun 93 in part (C.); and Victoria B. C., J. Macoun, without date (N. Y.).

Kylin (1941) established the genus *Orcasia* with Harvey's *Polysiphonia senticulosa* as the type species, and Kylin's photograph (fig. 33) represents a plant strikingly similar to the specimens of *P. Macounii* from the same general region. No authentic material of *Orcasia senticulosa* (Harv.) Kylin is available for examination and Kylin does not give figures of structural details. However, Macoun's specimens show no clear distinction between determinate and indeterminate branches, and the more indeterminate branches rarely if ever arise endogenously, but are mostly exogenous as indicated by the reduced number of pericentral cells in the basal segment and the absence of evidence of disturbance of the pericentral cells adjacent to the point of origin. No young branches were found arising endogenously from the base of determinate branchlets as described for *Orcasia*, and it seems doubtful if Macoun's plants can be identified with *O. senticulosa*. Some of the smaller branchlets are cicatrigenous in origin, and some of the erect branches seem to arise endogenously from the prostrate branches as in a number of species of *Polysiphonia*. Finally the main

axes of *P. Macounii* are usually corticated along the lines of juncture of the pericentral cells, whereas neither the original description of *P. senticulosa* nor Kylin's description of *Orcasia senticulosa* indicate that the plant is corticated. Lacking data concerning the origin of branches in relation to trichoblasts and concerning reproductive structures, critical comparisons with certain somewhat similar species of *Polysiphonia* are at present impossible. In general structural features *P. Macounii* is suggestive of *P. novae-angliae* Taylor from the New England region. The latter plant, however, is much more finely branched, with branches of all orders essentially similar, and the main axes are somewhat more completely corticated. From *P. fibrillosa* Grev. the west coast plant differs in color, in the spur-like branchlets, and in the lack of a discoid attachment organ. It differs from *P. subulata* (Dulc.) J. Ag. from Europe not only in the branching habit and the extent of cortication, but in the fact that branchlets are neither pectinate nor corymbosely fastigate as described for that species.

POLYSIPHONIA minutissima sp. nov. (fig. 21).—Plantae epiphyticae pusilles et cristatae, fere minus 3 mm. altae aut ad 6 mm., a crista rhizoidiorum ortae, qui in hospitem profunde penetrant; rhizoidiis e 1–3 cellulis compositis, interdum furcatis, cum apicibus obtusis et saepe aliquanto tumentibus, ad 1 mm. longis; ramis erectis cristatis, a fundamento assurgentibus; ramis complurum ordinum, exogenibus, ramis succedentibus per nulla intervalla constantia separatis; ramis principibus indistinctis, ad 145 μ crassis, cum segmentis fere unius diametri longis aut brevioribus; cellulis pericentralibus 4, omnino ecorticatis; trichoblastis brevibus, una per segmentum, in spira laeva cum $\frac{1}{4}$ declinatione, mox deciduis, cicatricellulas persistentes relinquentibus; tetrasporangiis in seriebus brevibus et spiralibus, ad 80 μ crassis, in ramulis ultimis tumentibus; cystocarpis paulo urceolatis, parce sessilibus, 225–290 μ crassis, trichoblastorum vicem; ramis antheridialibus circa 40 x 135 μ , ut unus ramus trichoblasti ortis, sine apicibus sterilibus; plantae obscure rubrae.

Plants epiphytic, diminutive, tufted, mostly under 3 mm. high or up to 6 mm. high, from a tuft of rhizoids deeply penetrating the host; rhizoids composed of 1–3 cells, often branched, with blunt and often swollen tips, up to 1 mm. long, cut off by a cross wall from the proximal end of the pericentral cells; erect branches assurgent from a prostrate rosette-like base, giving the plant the aspect of a diminutive tumbleweed; branches of several orders, exogenous replacing trichoblasts, with no constant interval between successive branches; main axes indistinct, up to 145 μ in diam., their segments mostly 1 diam. long or less; pericentral cells 4, totally ecorticate; trichoblasts short, one per segment, arising in a left hand spiral with $\frac{1}{4}$ divergence, soon deciduous, leaving persistent scar-cells; tetrasporangia in short spiral series, up to 80 μ in diam., causing the ultimate branchlets to bulge; cystocarps slightly

urceolate and nearly sessile, 225–290 μ in diam., replacing trichoblasts; antheridial branches about 40 x 135 μ , comprising one branch of a trichoblast, without sterile tips; plants dull red in color.

Type: Hollenberg 2554, collected from the middle or lower littoral zone on the bay side of Punta Banda, Lower California, Mexico, Dec. 17, 1938, growing on *Codium fragile* (Suhr.) Hariot. (H.). The writer has also collected a plant which is slightly larger but seems to belong to this species from the north side of Catalina Island, off the coast of southern California. The latter plant is up to 6 mm. high. The diminutive size and assurgent tufted habit of a tumble weed are the most distinctive features of *P. minutissima*, together with the single tuft of deeply penetrating and often multicellular rhizoids. The branching is somewhat unilateral in the case of the outer lower branches.

POLYSIPHONIA acuminata N. L. Gardner, New Rhodophyceae VI, Univ. Calif. Publ. Bot. 14:100, 1927. Plants erect, 2–6 cm. high, tufted, epiphytic or saxicolous, attached by a penetrating tuft of rhizoids arising from the base of erect branches, or having prostrate branches of limited extent which are attached by numerous rhizoids arising 1-many per segment; rhizoids unicellular and cut off by a cross wall from the pericentral cells; central percurrent axis prominent, 300–500 μ in diam., its segments mostly shorter than broad, with numerous densely branched laterals spirally arranged, resulting in slenderly conical or attenuate frond divisions; branches replacing trichoblasts, of several orders, with 2–6 (mostly 3) segments between successive branches; pericentral cells 4, relatively large, surrounding a small central cell, totally ecorticate; trichoblasts abundant 2–4 times forked, one per segment except when totally replaced by a branch, arising in a left hand spiral with $\frac{1}{4}$ divergence, soon deciduous, leaving scar-cells, the first trichoblast on a branch occurring 2–5 segments from the base of the branch, tetrasporangia 50–70 μ in diam., spirally arranged in swollen terminal branchlets; cystocarps numerous, nearly sessile, subspherical, 250–300 μ in diam.; antheridial branches measuring 100–150 x 30–50 μ , without sterile tip or with tip of 1–2 short sterile cells, arising as a primary fork of a trichoblast; plants medium to dark reddish brown, moderately adherent, growing in the upper littoral zone, chiefly in southern California.

The type material was collected by N. L. Gardner (no. 1968) at White's Point near San Pedro, Los Angeles County, California, June, 1908 (C.). It was distributed as Phyc. Bor.-Amer. no. 1599 under the name *Streblocladia camptoclada* (Mont.) Falk. Seventeen additional collections are available for study. Most of these were collected by the writer along the coast of southern California, including Catalina Island. One collection was made by N. L. Gardner in the Monterey region. The saxicolous specimens usually dry nearly black and have less distinct main axis, as compared with the epiphytic specimens. Usually the main axes are very straight and promi-

nent and the specimens are somewhat more delicate and a much lighter reddish or brownish color. The short segments in the main axes and the distinctness and straightness of these axes are in general the features which distinguish this species from *P. Snyderae* and *P. simplex* to which it is probably most closely related.

POLYSIPHONIA simplex sp. nov. (fig. 18).—Plantae saxicolae, saepe mattas densas aliquanto latas formantes, cum filamentis fundamentalibus repentibus et implicatis, 250–360 μ crassis, segmentis fere brevioribus uno diametro longis, per rhizoidia unicellularia a finibus proximalibus cellularum pericentralium abscissa et in discis lobatis terminata; filamentis prostratis ramos erectos 1–3–(7) cm. altos et 160–250 μ crassos cum axibus principibus distinctis et parce furcatis in modo exogene et assurgente producentibus; ramis exogenibus, in lateribus omnibus ortis; trichoblastis semel terque furcatis, in segmento una in collocazione spirale cum $\frac{1}{4}$ declinationibus ortis, mox deciduis, cicatricellulas persistentes relinquentibus; cum ramis trichoblastorum vicem, trichoblastis in origine non conjunctis; tetrasporangiis ad 70 μ crassis, in apicibus ramulorum aliquanto tumen-torum spiralliter dispositis; cystocarpis ovoideo-globosis, fere sessilibus, 300–350 μ crassis; ramis antheridialibus 100–170 x 35–40 μ crassis, furcis primis trichoblastorum ortis, sine apicibus sterilibus; plantae fuscae vel obscura-fuscae.

Plants saxicolous, forming dense mats often of considerable extent, with creeping tangled basal filaments 250–360 μ in diam., composed of segments mostly shorter than broad, attached by unicellular rhizoids with lobed tips, which are cut off from the proximal end of the pericentral cells by a curving wall; prostrate filaments giving rise in an exogenous assurgent manner to erect branches 1–3–(7) cm. high and 160–250 μ in diam., with main axes distinct but not prominent, and sparingly branched; branches exogenous, arising on all sides; trichoblasts 1–3 times forked, one per segment, arising in a left hand spiral with one fourth divergence, soon deciduous, leaving persistent scar-cells; branches replacing trichoblasts, not arising in connection with them; first trichoblast on a branch arising (1)–3–4 segments from the branch base; tetrasporangia up to 70 μ diam., spirally arranged in the somewhat bulging branch tips; cystocarps ovoideo-globose, sessile, 300–350 μ in diam.; antheridial branches arising from one fork of a trichoblast, measuring 100–170 x 35–40 μ , without sterile tips; plants medium to dark brown, drying nearly black, growing in the middle to upper littoral zone along the coast of southern California and Lower California, and possibly present in the Gulf of California.

Type: Hollenberg 2115, from rocks, Laguna Beach, Orange County, California, May 14, 1937 (H.). Additional representative specimens studied include: La Jolla, San Diego County, California, from boulders at low water mark, Mrs. M. S. Snyder, Phyc. Bor.-Amer. 246, issued as *Lophosiphonia willum* (J. Ag.) S. & G. (C., N. Y., Fi.); and from the

bay side of Punta Banda, Lower California, Mexico, Hollenberg 2563, Dec. 1938 (H.).

P. simplex is very common on sand-swept rocks in the middle littoral zone along the coast of southern California. It seems to be a perennial. In structural details it is close to *P. Snyderae* Kylin, as has been pointed out by Kylin (1941) in his discussion of Phyc. Bor.-Amer. 246. It differs from the latter species in habitat, in the densely matted habit with its much more extensive prostrate system of branches, and in having segments rarely longer than broad. In some cases the trichoblast primordia remain unicellular and directly constitute the scar-cells, as frequently occurs also in other species. In a number of detailed respects *P. simplex* is close to *P. ferulacea* (Suhr.) J. Ag., which has been recorded by Taylor (1928) from Florida and from the Danish West Indies by Boergesen (1919), but differs from the latter plant as described by these investigators in the low matted habit, in its slightly longer segments, and in the lack of sterile tips on the antheridial branches.

The writer has been privileged to examine a number of species of *Polysiphonia* collected by Mr. E. Yale Dawson in the Gulf of California. Nine of these the writer has placed provisionally with *P. simplex*. In Dawson's plants the segments are all very short, mostly less than half as long as broad. Hence they might better be placed with *P. ferulacea*, were it not for the low matted habit of *P. simplex*. Of special interest is the fact that in Dawson's number 284 from Puerto Refugio two tetrasporangia commonly occur in each segment. The other specimens are seemingly sterile.

POLYSIPHONIA *Masonii* Setchell and Gardner, Mar. Alg. Revill. Is., Proc. Calif. Acad. Sci. 19:160, 1930. Plants 2–3 cm. high, flaccid, attached by a bundle of short unicellular rhizoids with discoid tips; main axes 350–400 μ in diam. below, repeatedly and regularly dichotomously branched; pericentral cells 4, ecorticate, composed of segments hardly longer than broad in the main axis, shorter above; trichoblasts dichotomously or trichotomously branched, arising one per segment in spiral arrangement with $\frac{1}{4}$ divergence, deciduous, leaving persistent scar-cells; relation of trichoblasts to origin of branches not observed; tetrasporangia in spiral series in the ultimate branchlets, 85–95 μ in diam.; cystocarps subspherical, nearly sessile, 300–325 μ in diam.; antheridial branches arising from a primary branch of a trichoblast, broadly fusiform; plants reddish brown, epiphytic.

Type: H. L. Mason 86, on *Zostera*, Guadalupe Is., west coast of Mexico, April 1925, in the herbarium of the California Academy of Science. The above description is largely adapted from Setchell and Gardner's description after an examination of the type and only known material. In many detailed characteristics this plant is close to *P. Snyderae* Kylin, but the regularly dichotomous branching throughout and the somewhat discoid attachment organ, together with the lack of additional material, have made it

seem desirable to retain the name as a distinct entity at least for the present.

POLYSIPHONIA *flaccidissima* sp. nov. (fig. 8).—Plantae 10–20 mm. altae a filamentis repentibus; partibus prostratis 70–85 μ crassis, e segmentis fere 1.5 diametros longis, per rhizoidia unicellularia affixae; rhizoidiis variis longitudine, cum apicibus lobatis aut sine lobis, fere unum per segmentum, a finibus proximalibus cellulorum pericentralium abscissis; ramis erectis 70–80 μ crassis, cum segmentis 1–2 diametros longis et sursum brevioribus, exogenibus et assurgentibus a partibus repentibus, cum principibus axibus indistinctis; ramis aliquot vel multorum ordinum, omnibus exogenibus, cum trichoblastis in origine conjunctis ad utrumque terminum gradatim angustis, primum plerumque stristis et ad axem principem curvatis; cellulis pericentralibus 4, omnino ecorticate; trichoblastis simplicibus aut fere cum furcis singularibus saepe ad apicem incurvatis aut spiralibus, fere cum apicibus obtusis, una per segmentum in spira laeva cum $\frac{1}{4}$ declinatione, mox deciduis, cicatricellulas persistentes relinquentes; tetrasporangiis 50–70 μ crassis, in seriebus continuis aut interruptis, plerumque spiraliter in ramulis ultimis et subultimis ortis; cystocarpiis et ramis antheridialibus ignotis; plantae rubrae fere ad saxa et algas corallinas affixae.

Plants 10–20 mm. high from creeping basal filaments; prostrate portions 70–85 μ in diam., the segments mostly 1.5 diam. long, attached by unicellular rhizoids of variable length; rhizoids with or without lobed tips, usually one per segment, commonly two segments apart and cut off from the proximal end of the pericentral cells; erect branches 70–80 μ in diam., their segments 1–2 diam. long and shorter above, exogenous and assurgent from the creeping filaments, with indistinct main axes; branches of several to many orders, all exogenous and arising in connection with trichoblasts, narrowed gradually at both ends, at first usually strict and curving toward the main axis; pericentral cells 4, totally ecorticate; trichoblasts simple or mostly with a single fork; tapering only slightly to the blunt tips, which are often incurved or coiled, arising singly per segment in a left hand spiral with $\frac{1}{4}$ divergence, soon deciduous, leaving persistent scar-cells, or the scar-cells sometimes arising directly from undeveloped trichoblast primordia; tetrasporangia 50–70 μ in diam., in continuous or interrupted and usually spiralling series in the ultimate and subultimate branches, which are more or less swollen, each sporangium appearing above and spirally to the left of the scar-cell immediately below; cystocarps and antheridial branches unknown; color red; plants occurring on rocks and corallines, mostly in exposed places near high tide level along the coast of southern California.

Type: Hollenberg 2269, growing on corallines in shallow depressions on a large wave-swept rocky point at Laguna Beach, Orange County, California, Jan. 1, 1938. It is partly tetrasporic. The species in its typical diminutive form is represented by a number of additional collections by the writer at the same

locality and at other places, including a collection from Catalina Island and a collection as far south as Punta Banda, Lower California, Mexico. The latter collection was made on the bay side of the point in more sheltered water. All collections were made during the months of November to April inclusive and observations throughout the various seasons of the year at the type locality indicate that the plant is an annual at least as far as its appearance in the upper littoral zone is concerned, although var. *Smithii* was collected in the Monterey region in August.

P. flaccidissima is in general similar to *P. havanensis* Montagne as figured by Boergesen (1919, fig. 260, 261). The West Indian plant, however, is described as considerably larger, with leading branches more distinct, and with rhizoids continuous with the pericentral cells bearing them. Furthermore, the relative positions of the young branches and associated trichoblasts are seemingly different in the two species, and the Pacific coast plant rarely if ever bears adventitious branches as described by Boergesen for *P. havanensis*.

P. flaccidissima var. *Smithii* var. nov. (fig. 19).—Plantae 3–5 cm. altae, fere laxius ramosae quam in specie, cum axibus principibus ad 140 μ crassis et cum segmentis (2)–4–6 diametros longis; ramis fructiferis ignotis; plantae sublicis et saxis et conchis fere in aqua placida affixae.

Plants 3–5 cm. high, mostly more laxly branched than in the species, with main axes up to 140 μ in diam., segments (2)–4–6 diameters long; fruiting unknown; plants attached to piling, stones and shells in sheltered or deep water along the coast of central and southern California.

This variety is distinguished by its more luxurious habit, with larger branches and longer segments, and by the habitat. Number 1146 in the herbarium of the writer is considered the type collection. This collection was made from shells and stones near the highway bridge, Newport Bay, Orange County, California, Dec. 8, 1935. Three additional collections have been made: LaJolla, San Diego County, California, from wharf piling at low tide level, Hollenberg 1965, Dec. 1936 (H.); Pacific Grove, Monterey County, California, dredged from rocks at 35–40 ft., G. M. Smith, Aug. 1941, (Hop.); and San Francisco, from floats of Yacht Club, Feb. 1932, N. L. Gardner 6984 (C.).

POLYSIPHONIA Snyderae Kylin, Californische Rhodophyceen, Lunds. Univ. Årsskr. N.F. Avd. 2, 37:35, Taf. 12, fig. 34, 1941; (fig. 9); *Polysiphonia senticulosa* Snyder in Phyc. Bor.-Amer. 638, False Bay, San Diego, California, Jan. 1899, non *Polysiphonia senticulosa* Harvey.

Plants 5–12 cm. high, from a discoid base or mostly assurgent from a prostrate creeping base of limited extent, attached by unicellular rhizoids of variable length and mostly with lobed tips, arising 1–2–(5) per segment from the proximal ends of the pericentral cells from which they are cut off by a cross wall; erect branches 300–400 μ in diam. below, the

segments (0.5)–1–2–(3) diameters long, richly dichotomously branched and mostly naked below, the chief branches repeatedly alternately branched in a more or less dichotomous corymbose manner; pericentral cells 4, without cortications; trichoblasts numerous, arising one per segment in a left hand spiral with $\frac{1}{4}$ divergence, 2–3 times forked, soon deciduous, leaving persistent scar-cells; branches arising at irregular intervals, commonly 6–10 segments apart, in the trichoblast spiral, a branch completely replacing a trichoblast; tetrasporangia 60–70 μ in diam., in segments mostly one diameter long or slightly longer, in series in the ultimate and subultimate branchlets, slightly spiraling; cystocarps abundant, ovoid to nearly spherical on short pedicels of one segment, 300–350 μ in diam., replacing branchlets or trichoblasts in the spiral; antheridial branches comprising a primary fork of a trichoblast; plants dull or pale reddish brown to dull red, epiphytic on other algae or attached to wood, shells, etc., at low tide level, mostly in sheltered bays, Washington to southern California, and in the Gulf of California and south at least as far as the Revillagigedo Islands off the west coast of Mexico.

P. Snyderae is common in sheltered water of bays along the coast of southern California. In many respects it is similar to *P. simplex* and to *P. acuminata* but the segments in the main branches are distinctly shorter in both of these plants than in *P. Snyderae*. The matted habit of *P. simplex* is also distinctive, and as Kylin (1941) has pointed out, *P. Snyderae* is more dichotomous in its branching and has much less distinct main axes than *P. acuminata*. *P. Snyderae* is also similar in many respects to *P. tongatensis* Harvey, which De Toni (1903) places under *P. mollis* Hook. and Harv. The latter plant was described by Harvey (1847) from Tasmania. No specimens of *P. mollis* were available for examination, but judging by Harvey's description it seems possible that our plant may be identical with that species. In any case the writer is of the opinion that *P. tongatensis* (?) reported by Setchell and Gardner (1930) from the Revillagigedo Islands, and certain specimens in the herbarium of the New York Botanical Garden, which are labeled *P. tongatensis* and were collected in Hawaii, the Society Islands, and the Friendly Islands, are very close to if not identical with *P. Snyderae*. Also Robert E. Coker 124 and 126 (N. Y.) from Peru, referred by Howe (1914) to *P. abscissa* Hook. & Harv. are likewise probably referable to *P. Snyderae*. Furthermore, no 200528 in the herbarium of the University of California, which was collected in Japan and identified by K. Yendo as *P. urceolata* has most of the detailed structural features of *P. Snyderae*. *P. Snyderae* differs from *P. novae-angliae* Taylor in the absence of cortical filaments.

P. Snyderae var. *heteromorpha* var. nov. (fig. 15).—Plantae cum structura et ramis fructiferentibus ut in specie, sed cum ramulis numerosis accessoris et cicatrigenibus in partibus inferioribus axorum primariorum orientibus et aliquanto distinctioribus

quam in specie; ramulis fere brevibus, saepe aliquanto determinatis; plantae tenuiores quam species.

Plants with vegetative and reproductive structures mostly as in the species, but with numerous cicatrigenous branchlets arising in the lower parts of the main axes, which are somewhat more distinct than in the species; ultimate branchlets mostly short and often somewhat determinate; plants known only from the coast of Washington and the vicinity of Vancouver Island, British Columbia.

Type (fig. 15), N. L. Gardner 3837a, from pools in the middle littoral zone about three miles south of Cape Flattery, Washington, on the ocean side, May, 1917 (C. 276664). Several additional specimens in the herbarium of the New York Botanical Garden collected by John Macoun in the vicinity of Vancouver Island, may belong here, although they are coarser. The variety differs from the species chiefly in the numerous cicatrigenous branchlets and in the short, more or less determinate, ultimate branchlets.

P. Snyderae var. **intricata** var. nov.—Plantae cum structura et ramis fructiferentibus ut in specie, sed cum partibus inferioribus implicatis et intertextis.

Plants with the general features of the species but with more intricately branched and tangled filaments toward the base rather than with a single point of attachment as is common in the species.

Type: no. 3307 (Fi.) of Francis Drouet and Donald Richards, afloat four miles east of Guaymas, Sonora, Mexico, Dec. 1940. Several additional specimens are from the same general region. This variety differs from the species in the intricate and tangled

basal branches, the plant forming loose masses in which the individual plants are indistinguishable.

AUXIN AND CALINES IN SEEDLINGS FROM X-RAYED SEEDS¹

G. F. Smith and H. Kersten

It has been previously established by Went (1938a, 1938b) that certain specific factors other than auxin are involved in the growth of plants. These have been placed in a group of plant hormones termed "calines," having the essential character of being transported through living tissues only. Included are: rhizocaline, obtained from the cotyledons in the case of etiolated pea seedlings, which with auxin is responsible for root formation; caulocaline, formed in the roots, which is necessary in conjunction with auxin for stem elongation; and phyllocaline, a requisite for leaf growth which is auxin independent and, in the case of pea seedlings germinated in the dark, is derived solely from the cotyledons. The schemes of activity of these factors as correlated with auxin

in both light- and dark-germinated pea seedlings are diagrammed in figures 1 and 2.

Originally the presence and the differential character of the calines were indicated by tests in which the supply of one or another of the calines was experimentally removed by the excision of various plant parts. For example, a removal of the cotyledons from etiolated pea seedlings exhibited modifications in the elongation of stems in which growth in length ultimately ceased (Went, 1938a).

Additional evidence for the existence of calines as well as for their habit of transport through living tissues only, was assembled by performing experiments in which various amounts of calines were added by grafting experiments with peas using bases of varieties having different contents of some caline (Went, 1938b). In all instances it was found essential that in a graft union incorporating vascular tissue continuity be accomplished between stock and scion before any influence of the base type is exhibited (Hayward and Went, 1939).

The investigation described in this paper supplies further data for the presence of calines, and especially stresses their differential character as they are

¹ Received for publication April 20, 1942.

The writers gratefully acknowledge the kindness of Dr. F. W. Went in making available the facilities of the Wm. G. Kerckhoff Biological Laboratories of the California Institute of Technology where most of the physiological tests were carried out, and also for his suggestions and criticisms throughout the course of the investigation. Appreciation is also extended to Dr. D. M. Bonner for his interest in that portion of the investigation concerned with leaf growth factors and to Harriet Anne Kriete for capable assistance in carrying out leaf tests.

TABLE 1. Maximal growth rate, leaf and stipule surfaces, petiole and tendril lengths, of first, second and third leaf developed in Alaska pea seedlings of control seeds and of seeds given a small x-ray radiation treatment (30 kv, 10 ma, 8 cm. fifteen min.) after two weeks germination. Values given are the mean of forty plants.

	Length	Leaf Width	Surface	Petiole Length	Length	Stipule Width	Surface	Tendril Length	Maximal growth per day mm.

involved in the growth of both intact and grafted seedlings. One variety of pea seedling, Alaska, has been used, in which it has been found possible to alter the content of one or another of the calines in the seed by treating the seeds with x-rays prior to germination. Tests to determine auxin conditions in seedlings from x-rayed seeds are also given which indicate results comparable to those obtained by Skoog (1937) in his study on the effect of x-rays on auxin and plant growth.

Fig. 1-2.—Fig. 1 (left). Factors involved in dark-room-germinated peas.—Fig. 2 (right). Factors involved in light germinated peas.

METHOD.—For the x-ray treatment of the seeds, soft x-ray radiation was supplied by a copper target gas x-ray tube, equipped with a window of aluminum and cellophane which transmitted the $K\alpha$ and $K\beta$ lines of copper as well as the longer and shorter wavelengths in the continuous spectrum (Kersten, 1934). Because of the great amount of plant material required for the investigation, the seeds were oriented at random during treatment at a distance of 8 cm. from the focal spot of the x-ray tube which

was operated at 30 peak kv. and 10 ma. Under these conditions the intensity of the x-ray beam was approximately 2000 r/min.

The method of random orientation of course does not yield uniformly modified plant material because the side turned toward the target receives many times the dose received by the one turned away from the target. Since the pea embryo is so constructed that the plumule and radicle lie to one side, the effect of random orientation was that certain parts of the individual seeds received treatments ranging from very heavy to relatively very light. The variety of resulting modifications, however, was found to be of positive value during these particular experiments. Definite groups of commonly met x-ray induced plant abnormalities such as retarded stem, root or leaf growth could be uniformly assembled and studied by use of one x-ray treatment. A series of x-ray treatments employing oriented seeds would have been necessary were it desired to associate a specific plant modification with a specific dose of x-ray radiation. This information, however, is generally well known as is also the fact that any x-ray induced effect using random seed orientation can be produced more or less uniformly by some one x-ray treatment of oriented seeds.

All procedures were carried out in a physiological dark room, 24–26°C. and 85% humidity. The pea grafting technique employed was that described by Went (1938b). One-week-old etiolated pea seedlings were used. The stem portion between mid-first and mid-third internodes was removed by two oblique cuts made at the same angle by use of a small mitre box-like structure through which a razor blade could be passed over the stem. The cut surfaces of the remaining stem portions were brought into contact through a 5 mm. piece of glass tubing having a bore which approximated the diameter of the seedling stem.

After the graft preparation, measurements of the stem lengths were taken over a period of eighteen to twenty days, by which time maximal growth had been achieved in most cases; and at this time leaf, stipule, petiole and tendril measurements were generally recorded according to purposes of the par-

ticular experiment. Leaf measurements were supplemented by results of bio-assays for leaf growth factors as outlined by D. M. Bonner (1940) and by D. M. Bonner, A. J. Haagen-Smit and F. W. Went (1939). Auxin conditions were determined by the standard *Avena* test as specified by Went and Thimann (1937).

Throughout the paper, terms such as x-rayed or treated seedlings, tops, or bases, will be used to refer to seedlings or parts of seedlings from x-rayed seeds.

GROWTH OF INTACT SEEDLINGS WITH X-RAY MODIFIED CALINE CONTENT.—A number of experiments were run with Alaska peas from seeds given brief x-ray exposures. The treated seedlings as well as an equal lot of control seedlings were germinated individually in 20 cc. bottles. Daily growth rates were recorded for eighteen to twenty days, by which time maximal growth had generally occurred. Measurements of leaf, tendril, petiole and stipule of the first, second and third leaf developed were taken. Table 1 lists data from a typical test in which the exposure time was fifteen minutes. Leaf and stipule surfaces were calculated by determining the products of mean lengths and mean widths.

Data presented in the table indicate that the maximal growth rate value for both treated and normal intact seedlings, is relatively constant. Normal variations in Alaska peas generally fall within the range of 34–42 mm. per day, so that the slightly lesser value in the x-rayed set is probably of no experimental significance.

There is, however, a definite decrease in the size of foliar parts of all seedlings from the x-ray treated seeds. This is illustrated in figure 3.

GRAFTING EXPERIMENTS WITH PEAS FROM CONTROL SEEDS AND FROM X-RAYED SEEDS.—Later experiments were carried on with seedlings obtained from seeds exposed to x-rays for sixty minutes while oriented at random. Reasons for using this method have already been given. The types of seedlings obtained from seeds treated in this way can be arranged into four arbitrary groups, figure 4. These are: (1) normal maximal growth rate, reduced leaf size, normal root development; (2) reduced maximal growth rate (about one-third normal), reduced leaf size, normal root development; (3) reduced maximal growth rate (about one-tenth normal), normal root development; (4) reduced maximal growth rate (about one-tenth normal), poorly developed roots.

Grafting experiments with seedlings from group 1, employing various combinations of tops and bases of control and treated seedlings, gave results shown in table 2. The following effects are indicated: (1) uniform maximal growth rates for intact and grafted control and treated seedlings; (2) similar size of foliar parts of control-intact and of control-self-grafted seedlings; (3) similar size of foliar parts of x-rayed-intact and x-rayed self-grafted seedlings; (4) reduced size of all foliar parts of x-rayed-intact and of x-rayed-self-grafted seedlings as compared with values given for control seedlings; (5) decreased size of foliar parts of control tops grafted on x-rayed bases, as compared with normal leaf size; (6) increased size of foliar parts of x-rayed tops grafted on control bases, as compared with normal leaf size.

Apparently the effect of this particular x-ray seed treatment is on the phyllocaline supply which, in

Fig. 3–4.—Fig. 3 (left). Seedling tops from control seeds (left) and from seed given a fifteen-minute exposure to x-rays having an intensity of approximately 2000 r/min.—Fig. 4 (right). Seedling groups from seeds oriented at random while being exposed for sixty minutes to x-rays having an intensity of approximately 2000 r/min.

TABLE 2. Maximal growth rate, leaf surface, stipule surface, petiole and tendril lengths of first, second and third leaves of intact and grafted seedlings of control seeds and of seedlings grown from x-rayed seeds referred to as group 1 in figure 4. Mean values given represent fifteen to thirty plants.

dark-room-germinated seedlings, is available solely from the cotyledons. To check this conclusion further, assays for leaf growth factors were run, using methods described by D. M. Bonner, A. J. Haagen-Smit, and F. W. Went (1939). Seed diffusate of Alaska peas was used as a source of leaf growth factors. Circular disks of leaf tissue, 19.5 mm² in area, were cut from young primary leaves of radish. Twelve such disks were floated on 2 cc. of a culture medium in Syracuse watch glass dishes and grown for thirty hours at 25°C. Total wet weight of all twelve sections was determined by direct weighing. The culture medium consisted of 1 per cent sucrose plus various concentrations of a standard solution of pea diffusate, a standard solution having a dry weight of 10 mg. per cc. Diffusates of control and of x-rayed seeds were tested. Results of typical experiments are given in figure 5. Values given represent eight to sixteen assays.

In the assays using diffusate of seeds x-rayed for two hours before extraction, there is little if any leaf activity for concentrations of 0.5, 1.0 and 2.5 mg. dry weight diffusate per cc. of 1 per cent sugar over that obtainable in cultures on the basic 1 per cent sugar solution with no added diffusate. Some increase above the sugar value is meagerly represented when a dilution of 5.0 mg. of this diffusate is employed.

Diffusates of seeds x-rayed for four, six, and eight hours exhibit essentially no activity in promoting

leaf growth above or below the values recorded for the basic sugar medium in the concentrations tested (fig. 5). These extended x-ray treatments were included in the investigation to remove the possibility that the failure of the x-rayed seed extracts to support leaf growth might be ascribed to the production of some toxic substance in the cotyledons which prevented an increase in the size of the cultured leaf disks. If this rather than phyllocaline destruction were responsible, one would expect the effect to be more strongly exhibited with longer x-ray treatments. This does not occur. Also, if the effect of x-raying the seeds were the formation of some substance which inhibited the promotive effect of the seed extract on leaf growth, it ought to be possible to obtain some correlation between the degree of toxicity of such an x-ray produced agent and the concentration of the extract employed, so that the inhibitive effect would become more pronounced with increasing additions of the extract. In every case where higher concentrations are employed, the results fail to substantiate the existence of this relationship. The absence of such an effect is particularly evident in assays using the diffusate of the two-hour x-rayed seeds. As mentioned previously, the cultured leaf tissues responded positively to this extract when employed in dilutions of 5 mg. dry weight per cc. of the basic medium although lower concentrations failed to indicate leaf growth activity.

Fig. 5. Results of leaf assays using diffusates from non-irradiated peas and from peas irradiated for two, four, six and eight hours. The horizontal scale indicates the concentration of the seed diffusate employed in terms of mg. dry weight of diffusate per cc. of the basic medium of 1 per cent sugar. The vertical scale indicates the wet weight of the cultured leaf disks. Each value represented by ° indicates the total wet weight of twelve leaf disks. The vertical black lines represent the range of values derived from repeated tests for a particular diffusate dilution. Duplicate values are placed adjacent to each other. The range of growth values found for cultures on water and also for those on 1 per cent sucrose without added diffusate are also shown. In all cases the test period was thirty hours.

TABLE 3. Mean length in mm. of leaf, stipule, petiole and tendril of Alaska pea seedlings from control seeds and x-rayed seeds, the latter seedlings belonging to the group referred to as group 2 in figure 4. Measurements were taken of the first and second leaf developed, after maximal growth had been achieved.

	Leaf	Stipule	Petiole	Tendril	Maximal growth per day mm.

First leaves	4.8	4.5	3.6	3.6	43.7
Second leaves	6.7	5.4	8.4	6.6	

Results of grafting experiments with seedlings of the second group of treated plants (fig. 4), characterized by reduced leaf size as well as by reduced maximal growth rate, are listed in table 3. The following results are found: (1) leaf size effects, both in intact seedlings and in various grafting combinations, similar to those observed in the experiments with treated seedlings of group 1; (2) reduced maxi-

used, a reduced maximal growth rate is obtained; (4) when x-rayed base, control interstock, x-rayed top are used, a normal maximal growth rate is obtained.

Experiments designed to test phloem transport through the affected stem portions of treated seedlings by use of externally introduced indicators have been started, but conclusive results are not available to date.

AUXIN CONDITIONS IN SEEDLINGS FROM X-RAYED SEEDS.—Since auxin is also involved in stem elongation in conjunction with caulocaline, its presence was investigated in various stem regions of group 2 treated seedlings (fig. 4). Methods of determining auxin production, transportation, and destruction described previously by Michener (1937) were used. Quantitative results were obtained by the *Avena* test method.

Auxin production, as determined by the auxin diffusion tests from 1 cm. stem sections taken at intervals throughout germination, is found to be less during the first four to six days in the treated seedlings than in controls, but recovery is generally observed by the eighth day (table 5). Auxin transportation tests indicated no effect of the seed treatment.

Auxin destruction was found to be much greater in the stem portions of the treated seedlings than in controls. Typical results are given in table 6. The auxin destroyed is expressed in degrees of curvature of *Avena* coleoptiles (table 6). The effect of auxin destruction in the treated seedlings is seen to increase over controls from the stem apex to the base and to be more pronounced in older seedlings.

The condition of increased auxin destruction in the upper 1 cm. portion seems to have had no impeding effect on stem elongation when employed in grafted combinations of group 2 treated seedlings. The pronounced effect of auxin destruction in the basal portions of the treated seedling stems may, however, have significance in regulating the production of caulocaline or its transport from the roots. No information is available to support this relationship from experiments to date.

TABLE 4. Maximal growth rates in grafted Alaska peas incorporating interstocks using various combinations of control seedlings and of seedlings from x-rayed seeds. Values given are the mean of fifteen to twenty-five plants.

Seedling type	Maximal growth rate in mm./day
Control intact	42.5
Control top, interstock and base	35.9
Control top and base; x-rayed interstock	17.4
X-rayed top, base and interstock	12.0
X-rayed top and base; control interstock	37.7

mal growth rate of intact x-rayed seedlings; (3) normal growth rate of self-grafted x-rayed seedlings.

The only difference between the intact and the self-grafted x-rayed seedlings involved the removal of the mid-first to the mid-third internodal stem portion, as specified by Went's pea grafting technique. Consequently, if the problem were one of stem elongation factors, auxin or caulocaline, it would be a matter of transportation or destruction rather than of content. The significance of this mid-first to mid-third internode stem elongation of the treated seedlings is further indicated in grafting experiments employing interstocks. Representative data are given in table 4. The following results are recorded: (1) when control base, interstock and top are used, a normal maximal growth rate is obtained; (2) when x-rayed base, interstock and top are used, a reduced maximal growth rate is obtained; (3) when control base, x-rayed interstock, control top are

SUMMARY

A study has been made of the correlation between x-ray induced modifications and the conditions of auxin and calines in dark-room-germinated pea seedlings from seeds given x-ray treatments. The effects of treatments on auxin production, destruction and transport were determined by the usual test methods, and quantitative results were obtained by the *Avena* test method. Methods used to determine conditions of the calines included direct measurements of parts of intact seedlings and of grafted seedlings incorporating in various combinations, portions of control and treated seedlings. In the case of phyllocline, direct determination of the x-ray effect was made by testing diffusate from x-rayed seeds for leaf activity using the assay method of D. M. Bonner, A. J. Haagen-Smit and F. W. Went (1939).

Data indicated that auxin production and transport were relatively unaffected by the seed treatment, while auxin destruction was noticeably increased in seedlings from the treated seeds, particularly in the basal stem portions. Phyllocline was found by all test methods used to be definitely inactivated by the x-ray treatment, the extent of inactivation depending upon the intensity of the x-ray treatment. Seed diffusates from x-rayed peas produced little to no leaf activity in the leaf test. No apparent effect was found on caulocline production or activity, but the translocation of caulocline seemed to be hindered when higher x-ray doses were employed. This effect is concerned with the mid-first to mid-third internode region of the stem, since recovery in growth rate results in grafted seedlings in which this stem region has been removed. Various graft combinations, employing interstocks of this stem re-

gion taken from seedlings derived from x-rayed seeds, also show retarded stem growth.

The investigations described seem to indicate that the general types of x-ray induced structural modifications described thus far for plants can be explained on the basis of growth-factor destruction or transport inhibition. There seems to be no evidence to date supporting the view that growth inhibitors are synthesized by x-ray irradiation.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

THE EFFECT OF COLAMINE ON GROWTH AND PROTOPLASMIC STREAMING IN AVENA¹

Beatrice Marcy Sweeney

AS FAR as is known, there is no substance in animals comparable to the auxins which control the growth of plants. Extracts of animal tissues, however, contain substances which inhibit the growth of animal cells in tissue culture. Among these inhibiting substances is colamine, or ethanol-2-amine.

The history of the study of inhibitors extracted from liver is surveyed by Medawar (1937). In brief, liver extracts have been known for some time to have an inhibitory effect on cells in tissue culture. In 1926, Heaton made the first exhaustive studies of this factor in aqueous or dilute alcoholic extracts of adult liver. The extracts inhibited the growth of chick heart fibroblasts but had no effect on a number of different epithelial tissues. Heaton also extracted a similar factor from brewer's yeast, but the inhibition was probably due to malt present in the yeast extracts, since Heaton himself later showed that extracts of malt contained active inhibitors of this kind.

Substances inhibiting the growth of mesenchyme but not epithelium have been extracted from germinated and ungerminated barley, from the seeds of maize, wheat, and oats, from whole grain flour and even whole grain bread. The inhibitor has also been obtained in large quantities from whole oranges.

All the extracts contained yellow pigments in varying amounts, but removal of the pigment did not affect the activity of the inhibitor.

Brues and co-workers (1936) have recently studied the effect of these growth inhibiting factors on animal tissue cultures. They used saline or alcoholic extracts of liver to treat different embryonic and sarcomatous tissues. The radius of growth of cultures of fibroblasts was greatly diminished and there was a decrease in the wandering monocytes, although the life span of the treated cultures was not affected and rare mitoses could be found. Cells were smaller in treated than in untreated material. Epithelium was not affected. Brues et al. (1940) later identified colamine in the inhibitory extract. Colamine produced inhibition of growth in concentrations of 0.25 to 2 mg. per cc. A number of other amines were also active. The following study was undertaken to determine whether colamine has any effect on growth in plants comparable to its action on animal tissues, and to study the effect of colamine on protoplasmic streaming in plants, more especially to study its effect in the presence of auxin.

¹ Received for publication July 11, 1942.

The author wishes to express her appreciation to Professor K. V. Thimann for his very helpful suggestions and criticisms during the course of this investigation.

METHODS.—Seeds of *Avena sativa* Segerhavre strain were "husked" and soaked for two to four hours in tap water, and then laid out to germinate on moist filter paper in petri dishes. The plants were then grown in a dark room at 24°C. and 85 per cent relative humidity with occasional red light. Unless otherwise stated, the seedlings were used when four days old from soaking. The coleoptiles were then slit lengthwise and arranged on a slide and covered with a coverslip, so that the cells of the outer epidermis could be observed. The solutions used were added at one side of the coverslip and removed from the other side by a filter paper wick, so that a flow of solution under the coverslip was maintained.

The auxin used was recrystallized synthetic indole-3-acetic acid. The colamine was a synthetic preparation obtained from Hofmann La Roche. Dilutions of auxin and colamine were made up in 1 per cent fructose (Sweeney and Thimann, 1938). Unless otherwise stated, the solutions were oxygenated, and the pH was adjusted to neutrality (6.8) with HCl.

Streaming measurements were made by automatic recording (Sweeney and Thimann, in press) as well as with stop watch and ocular micrometer. Measurements of the effect of auxin and colamine together were repeated from time to time in three successive years.

Growth measurements were made using the section test of Schneider (1938). Sections of a known length were cut from the coleoptile and placed on combs floated on the solution to be tested. After varying periods of time, the length of the sections was measured with a microscope fitted with an ocular micrometer.

EXPERIMENTS ON PROTOPLASMIC STREAMING.—*The effect of colamine itself.*—Colamine in concentrations below 1000 mg. per liter did not bring about any consistent change in the rate of streaming. At a concentration of 10,000 mg. per liter, colamine brought about a fall in the rate of streaming and usually stopped streaming completely in fifteen to twenty minutes. Since colamine is a strong base, careful control of the pH was necessary. When the pH of the solution was not adjusted (pH 9) and no oxygen was bubbled through the solution, colamine concentrations of 1000 mg. liter also caused a decrease in the rate of streaming (fig. 1, curve 2), but either oxygenation or adjustment to pH 6.8 prevented this decrease. The effect of high concentrations of colamine was not due to high pH alone, however, since in solutions of NaOH at pH 9 the rate of streaming was not decreased (fig. 1, curve 4). Potassium malate 0.001M when added to a solution of colamine (1000 mg. per liter at pH 9 in unoxygenated water) prevented the decrease in the rate of streaming (fig. 1,

curve 3). From these experiments, then, no simple explanation may be offered for the effect of high concentrations of colamine. It may be noted that these are the concentrations (0.5 gr. per liter or above) which inhibit the growth of fibroblasts in tissue culture. Brues et al. (1940) also found alkaline solutions to be inhibitory in lower concentrations than solutions near neutrality. In general, the

Fig. 1-2.—Fig. 1 (above). The effect of colamine in 1 per cent fructose solution on the rate of streaming in four-day old coleoptiles. Curve 1: colamine 10,000 mg./l in unoxxygenated solution at pH 6.8, (5/4/39). Curve 2: colamine 1000 mg./l in unoxxygenated solution at pH 9, (2/23/40). Curve 3: colamine 1000 mg./l and malate 0.001M. in unoxxygenated solution at pH 9, (2/23/40). Curve 4: sodium hydroxide in unoxxygenated solution at pH 9. Curve 5:

effect of pH could no doubt be ascribed to its influence on the ionization of the colamine, the undissociated substance penetrating the cell more easily than the charged ion $\text{HO}(\text{CH}_2)_2\text{NH}_3^+$.

The effect of colamine with auxin.—In contrast to the high colamine concentrations necessary to produce an effect on the rate of protoplasmic streaming when auxin is not added, colamine in the presence of auxin acts in low concentrations comparable to active concentrations of other catalytic substances. The addition of colamine (3 mg. per liter or above) to solutions containing auxin prevented the stimulation of streaming which is produced in four-day old coleoptiles by auxin in concentrations of 0.01 to 1 mg. per liter (fig. 2, curves 1 and 2). Experiments testing the effect of colamine and auxin together on four-day old coleoptiles were repeated many times, and colamine always prevented the auxin from affecting streaming.

Since the acceleration of streaming by auxin requires ample oxygen supply, it might be suggested that colamine acts indirectly through increasing the oxygen consumption of the cell and hastening the onset of oxygen deficiency for streaming. That this is not the case was shown by experiments in which unoxxygenated solutions of colamine and auxin (1 mg. per liter) were used (fig. 2, curves 6 and 7). Under these conditions, but without the presence of colamine, the rate of streaming is decreased due to lack of oxygen (Sweeney and Thimann, 1938). With colamine present, auxin had no effect on the rate of

colamine 10 mg./l in oxxygenated solution at pH 6.8, (10/31/41). Each curve reproduced here is typical of several such experiments. Curves shown as continuous lines were obtained with automatic recording, those drawn through points were obtained by the stop watch method.—Fig. 2 (left). The effect of colamine in the presence of auxin on the rate of streaming in coleoptiles three to four days old. All solutions were made up in 1 per cent fructose at pH 6.8, and were added to the coleoptile preparation at time zero. Each curve reproduced below is typical of a number of such experiments. Curve 1: four-day old coleoptile treated with auxin 1 mg./l in oxxygenated solution, (7/21/41). Curve 2: four-day old coleoptile treated with auxin 1 mg./l and colamine 10 mg./l in oxxygenated solution, (7/21/41). A comparison of this curve with curve 1 shows that colamine inhibits the effect of auxin on streaming. Curve 3: four-day old coleoptile treated with auxin 1 mg./l, colamine 10 mg./l and malate 0.001M. in oxxygenated solution, (7/21/41). Malate thus prevents inhibition by colamine. Curve 4: three-day old coleoptile, used ninety min. after decapitation, treated with auxin 1 mg./l in oxxygenated solution, (4/4/40). Curve 5: three-day old coleoptiles used ninety min. after decapitation, treated with auxin 1 mg./l and colamine 100 mg./l in oxxygenated solution, (4/4/40). A comparison of curves 4 and 5 shows that colamine does not inhibit the effect of auxin on streaming in three-day old coleoptiles. Curve 6: four-day old coleoptile treated with auxin 1 mg./l in unoxxygenated solution, (1/24/39). Curve 7: four-day old coleoptile treated with auxin 1 mg./l and colamine 10 mg./l in unoxxygenated solution, (1/24/39). Curves shown as continuous lines were obtained with automatic recording, those drawn through points were obtained by the stop watch method.

streaming. Thus colamine simply removes the effect of auxin, whether the latter is positive or negative.

The nature of the effect of colamine on the response of the cell to auxin was made clearer by experiments in which the test solution contained auxin, colamine, and malate. Evidence that the four-carbon dicarboxylic acids, of which malate is representative, play a part in the fundamental reaction brought about by auxin is discussed in a previous paper (Sweeney and Thimann, in press). The effect of malate in four-day seedlings was to remove the inhibition of auxin caused by colamine. Solutions containing auxin, colamine and malate accelerated streaming to the same degree as did controls containing auxin alone (fig. 2, curve 3).

In this connection it is of interest to note that colamine did not inhibit the effect of auxin on the rate of streaming in three-day old coleoptiles (fig. 2, curves 4 and 5). The data of Commoner and Thimann (1941) and the experiments on old coleoptiles reported in a previous paper (Sweeney and Thimann, in press) provide evidence that the supply of four-carbon acids is depleted as the seedling grows. The four-carbon acids present in three-day old plants may be sufficient to overcome the effect of colamine.

GROWTH EXPERIMENTS.—The streaming data suggested that colamine might act as an inhibitor of growth. To test this possibility, growth of coleoptile sections was measured in fructose solutions containing either auxin or auxin plus colamine and in fructose solutions alone. The pH of all solutions was 6.8. Sections were cut from three-day old plants. No inhibition of growth was found in colamine (100 mg. per liter or 10 mg. per liter). Concentrations of 1000 mg. per liter inhibited growth about 50 per cent (see table 1):

TABLE 1. Inhibition of growth by colamine. The auxin concentration used was 1 mg. per liter; colamine, 1000 mg. per liter. All solutions were made up in 1 per cent fructose at pH 6.8.

Per cent elongation of sections after twenty-four hours in:			
Auxin	Auxin and colamine	Sugar alone	Per cent inhibition by colamine
76	33	17	57
60	39	18	35

In several, although not all, of the experiments with low concentrations of colamine, sections treated with auxin and colamine continued to grow for a longer time than those in auxin and, thus, actually reached a greater length (fig. 3). This suggests that the effect of colamine is to spare some substance (not auxin) which is necessary for growth. To test this possibility, preliminary experiments were made in which sections were kept in colamine for a time before being placed in auxin. These sections grew very little, due to aging before the addition of auxin. Heyn (1934) has shown that aging may be pre-

vented by cold. Therefore, sections were pretreated in the dark at 3°C. The sections were pretreated with colamine, auxin, malate and sugar alone for twenty-four and forty-eight hours. At the end of this time, the sections were transferred to auxin or auxin plus malate and allowed to grow at 25°C. Cold

Fig. 3-4.—Fig. 3. The effect of colamine on elongation of coleoptile sections in solutions containing auxin. Three mm. sections cut from etiolated coleoptiles sixty-nine hours from soaking were placed in 50 cc. 1 per cent fructose solution containing auxin 1 mg./l (○), auxin 1 mg./l and colamine 100 mg./l with fructose (×), or sugar alone (Δ) all at pH 6.8. The solutions were renewed after nine hours. Each point is the mean elongation of thirty sections from ten plants, (3/29/40).—Fig. 4. The effect of pretreatment with colamine on the growth of sections subsequently placed in auxin solution. Three mm. sections cut from coleoptiles 71½ hours old from soaking (12/9/40) were placed in 50 cc. of 1 per cent fructose solution containing auxin 1 mg./l (○), auxin 1 mg./l and colamine 100 mg./l (●), colamine 100 mg./l (×), or sugar alone (Δ), all at pH 6.8. After twenty-four hours (at arrow on the abscissa), the sections previously in colamine (see curve marked C→A) or sugar alone (see curve marked S→A) were transferred to auxin solution 1 mg./l and the auxin and auxin plus colamine solutions were renewed. All solutions contained 1 per cent fructose. Each point is the mean elongation of thirty sections from ten plants.

Fig. 5-6.—Fig. 5. The effect of a twenty-six hour cold treatment on elongation. Three mm. sections cut from etiolated coleoptiles 68½ hours old from soaking (9/2/41) and still containing the leaf were placed in 10 cc. of 1 per cent fructose solution containing auxin 1 mg./l (●), colamine 100 mg./l (×), malate 0.001M. (Δ), and sugar alone (○). After twenty-six hours at 3°C. in the dark, sections in colamine or sugar alone were transferred to auxin 1 mg./l, those in malate, to auxin 1 mg./l and malate 0.001M., while sections in auxin were placed in fresh auxin solution. All solutions contained 1 per cent fructose. Further growth took place at 24°C. in the dark. Each point is the mean elongation of thirty sections from ten plants.—Fig. 6. The effect of a fifty-hour cold treatment on elongation of sections. Three mm. sections cut from etiolated coleoptiles 71½ hours old from soaking (9/9/41) and still containing the leaf were placed in 10 cc. of 1 per cent fructose solution containing auxin 1 mg./l (●), colamine 100 mg./l (×), malate, 0.001M. (Δ), and sugar alone (○). After fifty hours at 3°C., sections in colamine and sugar alone were transferred to auxin 1 mg./l, those in malate, to auxin 1 mg./l and malate 0.001M., while sections in auxin were placed in fresh auxin solution. All solutions contained 1 per cent fructose. Further growth took place at 24°C. in the dark. Each point is the mean elongation of thirty sections from ten plants.

treatment considerably slowed the aging process. After twenty-four hours' cold, all the sections including the sugar controls grew as well as three-day old plants upon being removed from the ice box and transferred to auxin (fig. 5). It may be noted in passing that during the cold period, sections in auxin grew significantly more than did those without auxin, showing that growth is not prevented by temperatures which almost completely stop deposition of secondary wall, thus corroborating earlier observations of Heyn.

If the cold treatment was for forty-eight hours (fig. 6), then sections soaked in colamine or malate retained the ability to react to auxin better than did sections soaked in sugar. Aging due to exhaustion of factors necessary for growth seems to be operative here. These results add support to the hypothesis that colamine spares a growth promoting substance, possibly a four-carbon acid.

The question arose as to whether this sparing effect could also be demonstrated by streaming measurements. It was found in other experiments (Sweeney and Thimann, in press) that three-day old coleoptiles, sectioned and soaked in sugar solution or water for twenty-four hours, lost the ability to react to auxin with an acceleration of the rate of streaming. Since streaming is unaffected by thickening of the cell wall, it was concluded that substances other than auxin were depleted during soaking and that, since malate restored the activity of auxin, these lost substances were probably four-carbon acids. Therefore, sections were soaked overnight in colamine (100 mg. per liter), controls being soaked in sugar solution alone. The following day these sections were treated with auxin 1 mg. per liter while

records of the rate of streaming were made (fig. 7). As expected, those coleoptiles, soaked only in sugar solution, showed no acceleration of streaming on the addition of auxin, while sections soaked in colamine responded to auxin with as large an acceleration of streaming as did intact four-day old plants.

DISCUSSION.—In *Avena* coleoptiles, an effect of colamine may be detected at concentrations considerably lower than those inhibiting growth of fibroblasts in tissue culture. The immediate effect of low concentrations of colamine appears from data on streaming to be an inhibition of the effect of auxin, while growth measurements suggest that, after longer periods of time, colamine may act to promote

Fig. 7. The effect on the acceleration of streaming caused by auxin of soaking coleoptile sections overnight in colamine. All solutions were made up in oxygenated 1 per cent fructose. Similar results were obtained in two other such experiments. Curve 1: sections from three-day old coleoptiles soaked twenty-four hours in 1 per cent fructose, and treated at time zero with auxin 1 mg./l and at twenty-eight min. with auxin 1 mg./l and malate, 0.001M., (7/19/41). Curve 2: sections cut from three-day old coleoptiles and soaked twenty-four hours in colamine 10 mg./l in 1 per cent fructose solution and treated at time zero with auxin 1 mg./l (7/19/41).

the growth reaction. This contradictory evidence at once suggests that colamine is not simply an auxin inhibitor, but acts indirectly on the growth mechanism, probably through an effect on the availability of the four-carbon acids. A possible mechanism might be the formation of a relatively unstable compound of colamine with one of the four-carbon acids, which may dissociate in time, setting free again the four-carbon acid. This compound is not a salt, since at pH 6.8 a salt would be dissociated immediately. A linkage of the NH_2 of colamine with $\text{C}=\text{O}$ as in oxaloacetic acid is a possibility. The immediate effect of colamine would thus be to remove four-carbon acid from the reaction causing immediate auxin inhibition, and to preserve this acid in the form of a compound from which it is later set free. If this liberation takes place at a time when growth is limited by the four-carbon acids, then colamine will appear to accelerate growth.

The possibility exists that a similar tying up of the four-carbon acids may account for the inhibition of growth of animal cells, in which it is thought (Szent-Györgi, 1937, 1939) that most, if not all of respiration involves the four-carbon acid cycle. Both Medawar and Brues noted extremely rapid growth of inhibited cultures as soon as the inhibiting solution was removed. As in plants, susceptibility to colamine increases with increasing age, both of the tissue and of the culture. It may be suggested that the influence of the addition of malate on the growth of fibroblasts is well worth study.

SUMMARY

Colamine, one of a number of amines which inhibit the growth of fibroblasts in tissue culture, was found

to retard the rate of streaming in oat four-day old coleoptiles, but only at very high concentrations, 1000–10,000 mg. per liter.

Lower concentrations of colamine (3 mg. per liter or more) at pH 6.8 inhibited the acceleration of streaming brought about by auxin in four-day old coleoptiles, both in oxygenated and in unoxygenated solutions.

This inhibition was removed by the presence of 0.001M malate.

Growth studies showed that colamine does not inhibit the growth of sections of three-day old coleoptiles. In solutions of auxin and colamine, growth sometimes continued longer than in auxin alone.

When coleoptile sections were soaked overnight in various solutions, aging being prevented by carrying out this preliminary treatment at 3°C ., their subsequent ability to grow in auxin solution was maintained. If the cold treatment was forty-eight hours, the subsequent growth in auxin of sections pretreated with either colamine or malate was greater than that of sections pretreated with either auxin or sugar alone.

Streaming of coleoptiles cut when three days old and soaked overnight in colamine (100 mg. per liter) was accelerated on the addition of auxin, while coleoptiles soaked in sugar alone did not show acceleration of streaming on the addition of auxin.

It is concluded that colamine acts by making temporarily unavailable a substance necessary for the action of auxin, possibly a four-carbon acid.

THE USE OF RADIOACTIVE PHOSPHORUS IN TRANSLOCATION STUDIES¹

Robert N. Colwell

ONE of the most difficult problems in the study of rapid solute transport in plants is to limit the solute being studied to a single conducting tissue so that one can accurately observe the factors determining its rate and direction of movement. The work of Mason and Maskell (1928) and of Stout and Hoagland (1939) indicates that a ready transfer of solutes may take place between xylem and phloem by cell-to-cell diffusion accelerated by protoplasmic streaming. By the same means solutes may move longitudinally at rates as high as 2 cm. per hour (Crafts, 1939) through channels entirely distinct from the sieve tubes and vessels that are regarded as the normal conduits for rapid longitudinal movement. Failure to distinguish this accelerated cell-to-cell diffusion from rapid longitudinal transport has led to many questionable interpretations from experiments designed to elucidate the mechanics of translocation. For this reason Caldwell's translocation studies (1936) using viruses have been criticized; also Schumacher's fluorescein experiments (1933, 1937), the work of Fischer (1936), and Both (1937) with nitrogen compounds, and Gustafson and Darken's translocation studies (1937) using radioactive isotopes.

All these experiments have been criticized (Crafts, 1939) because rates greater than those of cell-to-cell diffusion accelerated by protoplasmic streaming were not demonstrated, so that conclusions relevant to the mechanism of rapid solute transport were not justified.

Several workers have used radioactive isotopes as indicators in experiments on solute transport in plants. Gustafson and Darken (1937) have already been mentioned. Stout and Hoagland (1939) used oiled paper to separate bark from wood for a short distance along stems of willow and geranium. They found that radioactive isotopes of potassium, sodium, or phosphorus introduced in the solution around the roots of these plants subsequently appeared in the wood but not in the bark of the separated region. Wherever the phloem was left attached to the xylem, however, it contained the test element almost as soon as the xylem itself. These observations point to the xylem as the sole channel for rapid upward transport of water and salts in the stem below the principal transpiring region. They also indicate the rapidity with which salts diffuse radially from xylem to phloem.

More recently Biddulph (1941) has studied the migration of injected radiophosphorus from bean leaves. He injected the terminal leaflet of the second alternate leaf of each plant as follows. While the blade was held under water he dissected out the

principal lateral vein of the leaflet to form a flap. This flap was immediately dipped into a small container of radiophosphorus, left for five minutes, and then removed to a special container of water. After a few hours he ashed various fractions of the plant, analyzed them with a Geiger counter, and found radioactivity in the stem both above and below the node of the treated leaf. Since the plant was actively transpiring, he concluded that the radiophosphorus had been transported upward in the xylem and downward in the phloem.

The work of Strasburger and Dixon on dye movement in the xylem, however, and more recent work on xylem injection indicate that with Biddulph's injection method no clear differentiation can be made between xylem and phloem movement. His experiments are, therefore, of doubtful significance with respect to the direction, localization, or mechanism of normal solute movement in plants.

In using radioactive isotopes in physiological experimentation one should remember that they may affect cell permeability. As early as 1926 Fricke (1926) showed that beta and gamma rays can denature proteins. Barnett (1939) points out that electrically asymmetric lipoidal molecules such as those found in cell membranes may change their polar properties when bombarded with electrons or gamma rays, and that, according to Wilbrandt (1935), any such change will alter the permeability of the membrane.

Crane (1939) asserts, "It is unnecessary to consider the *local* effect of a particular radioactive atom upon a cell which happens to be close to it." He further states that the effect on permeability depends upon the magnitude of the generalized dose of ionization delivered to the material throughout its volume. The beta rays emitted by radiophosphorus must affect permeability much as x-rays do, since the latter produce rapidly moving electrons. Heilbrunn and Mazia (1936) have reviewed experiments dealing with the effect of x-rays on permeability. In general no effect is noted below an activity equivalent to about 10^6 disintegrations per cc. per second, which is roughly equivalent to a strength of 20 microcuries of radiophosphorus per cc. of solution.

In the experiments to be described, solutions having strengths as high as 100 microcuries of radiophosphorus per cc. were placed on the leaf. By its effect on cell permeability this radioactivity may have facilitated the penetration of radiophosphorus into the leaf, but so little of this substance eventually migrated out of the leaf in these experiments on phloem transport that there was probably little effect on permeability in the conducting elements themselves, if Crane's values are correct. Crane has apparently neglected, however, to consider the probability that plant cells will accumulate radioactive salts from the bathing solution and by thus concen-

trating them will induce a local radioactivity far in excess of this generalized dose of ionization.

Mullins (1939) has studied the rate of uptake of radioactive sodium by *Nitella*. According to him there is no effect on permeability at doses below 1 microcurie per cc. of solution, but at strengths of 1 to 50 microcuries per cc. the rate of penetration of sodium is *inversely* proportional to the log of the dose. He obtained similar results with radioactive potassium and again with x-rays as the radiant source. However, his experiments were run for periods of only a few hours.

As Mullins (1939) has pointed out, the radiations from various radioactive isotopes differ so markedly that a different limit of biological effect must be made for each one. Hevesy (1940) finds little indication of injury to tissues from radioactive indicators when used in low concentrations. In his experiments on red blood cells he calculates that only one Na^{24} atom was used per 1000 cells and that only one in ten of those disintegrated during the experiment. In interpreting results of translocation studies one should certainly consider the radioactivity of the solution used and its consequent effects on cell permeability. At present, however, our knowledge of threshold concentrations and of precise biological effects is inadequate for a detailed interpretation with respect to mechanisms of the type involved in the transport of solutes in plants. Permeability effects are probably more pertinent in absorption studies than in translocation work; in the latter, rates of movement are such that little injury to a single conducting element could occur while the necessary amount of tracer is moving through it. Although often in the experiments described in this paper far more than the necessary amounts of radioactive phosphorus were injected into leaves, no injury attributable to the tracer was found at any time.

EXPERIMENTS ON THE CHANNEL OF TRANSPORT OF RADIOACTIVE PHOSPHORUS.—Hubbard squash plants were grown in the greenhouse in Hoagland's water culture solution with forced aeration. When these were two months old and were growing very rapidly, four healthy ones were selected for experimentation.

Figure 1 shows some of the plants. In plants 2 and 4 (table 1) the petiole of the leaf to be treated was

tionless for rapid conduction. Apparently, it did not impair conduction in the xylem.

In treating each plant, a plasticine ring was carefully molded on the middle of the upper surface of one leaf; and at 7:30 P.M. into the well thus formed was poured about 10 ml. of an aqueous solution containing a total of 150 mg. of Na_2HPO_4 in which was approximately 1 millicurie of radioactive phosphorus (P^{32}).

The plants were collected after the periods indicated in table 1, and each stem was immediately cut up into segments. To determine the distribution of radioactive phosphorus, cross sections of the stem were cut at various levels above and below the node of the treated leaf, and radioautographs of them were made by placing the sections on a thin piece of aluminum foil directly over a piece of Eastman no-screen x-ray film. If the sections contained no radioactive phosphorus, the film was not affected, but the portion of it immediately beneath any tissue containing radioactive phosphorus was activated.

To secure clarity of the radioautographs, the following steps were taken:

1. The sections were pressed closely to the film with rubber-band wrappings, after first backing the film with cardboard to give it rigidity and placing a piece of paper toweling immediately over the freshly cut sections to absorb moisture squeezed from them.

2. Since x-ray film is very sensitive to light, the sections were mounted in the dark-room and placed in light-tight boxes.

3. For clear radioautographs, exposure periods of forty-eight hours or more were usually necessary. To reduce diffusion of phosphorus within the tissues of the sections during these prolonged exposure periods, cold temperatures were maintained by keeping the light-tight boxes and enclosed films in a refrigerator.

Table 1 gives details of the treatment for each plant.

Since it was desired to compare the final distribution of phosphorus in plant 1 with that in plant 2 by means of radioautographs, the stem sections cut from plant 1 and from plant 2 were placed over a single film in order to give all sections identical exposure and development. For the same reason all cross-sections were cut to approximately equal thickness, 200 microns, in a hand microtome. Each horizontal row contained five serial sections taken from the same level.

Figure 2 shows the results of this experiment as shown by radioautographs. Sections from plants 3 and 4 were radioautographed in a similar manner for comparison.

As figure 2 shows, scalding the petiole prevented export of radioactive phosphorus from the leaf in

Fig. 2. Radioautographs of stem cross sections from plants 1 and 2 cut at the levels indicated on the right. Sections are 200 microns thick. Exposure period 2 days. Sections from plant 2 though barely discernible on the negative are lost in the process of reproduction.

plant 2 for the entire forty-hour period even though the xylem was still functional. This fact indicates that export of radioactive phosphorus in plant 1 must have been through the phloem.

Fig. 3-4.—Fig. 3. Radioautograph of treated leaf from plant 1 with normal petiole. Dashed white lines indicate lower margins of leaf and veins that were barely discernible in the negative.—Fig. 4. Radioautograph of treated leaf from plant 3 with scalded petiole. Plugging of the phloem of the petiole hindered export of radioactive phosphorus from the leaf. Movement within the leaf resulted in a thorough distribution in all veins.

Figure 3 is a radioautograph of part of the treated leaf of plant 1 and figure 4 of plant 2, both having been made at the end of the experiment. There is a much more complete distribution of radioactive phosphorus within the treated leaf in plant 2 than in plant 1, even though the same area was treated and for the same length of time in each case. The explanation is probably that in plant 1 much of the radioactive phosphorus could move directly out of the leaf via the phloem (fig. 3), whereas in plant 2 the phloem of the petiole had been plugged by scalding, so that distribution was confined to the leaf itself (fig. 4).

As was shown by radioautographs of stem sections from plants 3 and 4, large amounts of phosphorus moved back through the unscalded petiole in plant 3 and equally large amounts through the scalded petiole of plant 4, even though the plants were collected

only three hours after treatment. As table 1 reveals, approximately four times as large a surface was flooded in the treated leaf of plants 3 and 4 as in the treated leaf of plants 1 and 2. Thus, while only 10 to 15 per cent of the leaf was flooded in plants 1 and 2, 40 to 60 per cent was flooded in plants 3 and 4. These plants when treated were apparently under a considerable water deficit, as was evidenced by their partially wilted condition. In this state the whole xylem system tends to withdraw water from any possible source. In plants 1 and 2 so little of the leaf was flooded that whatever liquid entered the xylem of the veins was probably transpired within the leaf itself and consequently never moved down the petiole, via the xylem, since the transpiration stream was still moving from stem to leaf through the petiole. In plants 3 and 4, however, a much larger area of the leaf was flooded; not only did more of the solution get into the xylem of the leaf veins, but the total transpiration of the leaf was reduced. In consequence, apparently, the flooded leaf was a source of water for the rest of the plant, and the solution moved out of the leaf via the xylem of the petiole. This entire experiment was repeated, with similar results.

In other experiments, whenever a leaf vein covered by the solution was ruptured, or whenever the flooded area of the leaf was first scalded or killed with ether, radioactive phosphorus moved back through the scalded petiole even though a very small area of the leaf had been flooded. This fact indicates how much care must be exercised in treating leaves to assure export from them in the phloem only. The experiments also show that scalding the petiole does not seriously impair conductivity of its xylem elements, at least within the experimental period. The fact that the leaves did not remain wilted throughout the night, even though their petioles were scalded, whereas comparable leaves cut from the plant wilted rapidly, also indicates that the xylem was still functional despite scalding. It appears from these experiments that the downward movement of radioactive phosphorus in bean stems, reported by Bidulph (1941), may have been, contrary to his conclusions, largely in the xylem rather than in the phloem, since he cut open the veins and submerged them in a solution containing radioactive phosphorus.

If plants were kept in a saturated atmosphere before treatment, no doubt a much larger area of a leaf could be treated without danger of export via the xylem.

EXPERIMENT ON THE DIRECTION OF TRANSPORT OF RADIOACTIVE PHOSPHORUS.—Five healthy plants varying in length from 245 cm. to 360 cm. were selected, and on each plant one leaf was treated in the manner previously described. A solution containing phosphorus of approximately the same radioactivity as in the previous studies was applied. In this experiment, however, a Geiger counter was used rather than radioautographs to determine the distribution of radioactive phosphorus.

The counter was kept in a fixed position throughout, to minimize variations in the background reading. The counter was surrounded on all sides by lead and on top by a lead shield in which a slit approximately one inch long and one-half inch wide was cut directly over the counter.

Fig. 5. Experiments on the direction of transport of radiophosphorus. Movement apparently paralleled that of foods in the plant. (Counts per minute given have not been corrected for the background count.)

Figure 5 illustrates these experiments. Each value reported is an average for ten one-minute readings made at the region of the plant indicated, by holding that portion of the intact plant directly over the slit in the lead shield. Since all portions analyzed were held in very nearly the same position with respect to the counter, the values are believed to indicate relative concentrations quite accurately.

To be certain that most of the radioactive phosphorus was exported from the leaf via the phloem rather than the xylem, two control plants were simi-

larly treated except that the petiole of the treated leaf was first scalded. One control analyzed eighteen hours after treatment, gave 37 counts per minute at the node of the treated leaf and only background values (29 counts per minute) elsewhere in the stem. The second control, analyzed nineteen hours after treatment, gave 35 counts per minute at the node of the treated leaf and only background values elsewhere in the stem.

In plant 5, as figure 5 shows, the lowermost remaining leaf was treated; and movement from it was predominantly toward the roots, which constituted the nearest sink for organic solutes. The two leaves below the treated one indicated in figure 5 were removed before the experiment. Since there was no appreciable upward movement of radiophosphorus in plant 5, even after seventeen hours, there was probably little xylem transport of radiophosphorus diffusing radially from phloem to xylem.

In plant 6 the leaf treated was near the middle of the shoot, and movement during the eighteen-hour period was both upward and downward, either because of an alternate upward and downward movement in the stem, or because of simultaneous movement in both directions.

In plant 7 (fig. 5) a leaf near the shoot tip was treated. Movement from it was predominantly toward the shoot tip, which constituted the nearest sink for organic solutes.

According to these results, movement of radioactive phosphorus, if restricted to phloem, is predominantly in the direction of food movement from the treated leaf.

EXPERIMENTS ON THE RATE OF MOVEMENT OF RADIOACTIVE PHOSPHORUS.—Figure 6 shows results of an experiment designed to study with the Geiger counter the rate of downward movement of radioactive phosphorus from a leaf on which was placed a radioactive phosphorus solution in a small plastic well.

To determine whether or not this radioactive phosphorus arrived at the base of the stem much sooner than is indicated by the Geiger counter, but in amounts too small to be detected by it, the following experiment was performed.

Six healthy squash plants were carefully selected, each between 300 and 400 cm. in length. In every case the radioactive phosphorus solution was placed on a leaf attached approximately 100 cm. below the shoot tip. The time was 6:30 P.M. One hour after treatment one of the plants was collected. Sections were cut from its stem just above the cotyledons, and radioautographs of them were made by placing the sections on aluminum foil over a piece of x-ray film, as previously described. The five remaining plants were similarly analyzed, three, six, sixteen, twenty, and twenty-four hours, respectively, after treatment. The radioautographs revealed that the plants collected sixteen, twenty, and twenty-four hours after treatment showed unmistakable evidence of radioactive phosphorus in the vascular bundles of the stem at the level of the cotyledons. In each case,

Fig. 6. Experiment on the rate of downward movement of radiophosphorus as shown by the Geiger counter.

however, readings with the Geiger counter on this portion of the stem failed to give average values different from the background reading. Apparently, then, the Geiger counter is useful in detecting only fairly large concentrations of radioactive phosphorus in a given portion of the intact plant, and therefore the rate of downward movement of radioactive phosphorus from the plant shown in figure 6 was probably much more rapid than the Geiger counter indicated.

Obviously, in the experiments just described, some time was required before an appreciable amount of the solution containing radioactive phosphorus could diffuse through the cuticle and epidermis of the leaf and come in direct contact with the mesophyll tissues and veins. A method of vacuum infiltration was devised, accordingly, whereby large quantities of the solution could be taken directly into the leaf in a very short time.

The apparatus in position, surrounding a leaf, is roughly sketched in figure 7. The 200-ml. wide-mouth bottle was three-fourths filled with an aqueous solution containing a total of approximately 150 mg. Na_2HPO_4 in which were about 5 millicuries of radioactive phosphorus.

In infiltrating the leaf, the lamina was first carefully rolled up and dipped into the bottle of solution, while the petiole was inserted into a slit in the rubber cork that plugged the top of the bottle. A hole in the cork accommodated one end of a tube that

extended directly to a suction pump attached to a water faucet. Leaks in the cork where the petiole was inserted were sealed with plasticine.

As suction was applied, air was withdrawn through the stomates of the leaf from the spongy interior and bubbled up through the solution. After about thirty seconds, suction was rapidly released, and the system allowed to return to atmospheric pressure, whereupon the solution containing radioactive phosphorus entered the leaf almost immediately to replace the air withdrawn, giving the leaf a water-logged appearance. Thus the solution came directly in contact with the veins and mesophyll cells inside the leaf. About fifteen seconds after suction was released, the bottle was removed. Usually within about fifteen to thirty minutes the excess moisture in the leaf has been absorbed or transpired so completely that the treated leaf was indistinguishable from other leaves on the plant, and was, therefore, not noticeably injured by the vacuum infiltration treatment.

That this method resulted in rapid distribution of large quantities of radioactive phosphorus throughout the plant is shown by figure 7, which

Fig. 7. Effect of vacuum infiltration on rate of phosphorus movement. Readings were made with the Geiger counter, 3 hours after infiltration.

gives readings only three hours after treatment. This plant should be compared with plant 6 of figure 5, in which a plasticine well was used.

Scalding the petiole of a leaf treated by vacuum infiltration fails to prevent this rapid movement, which, therefore, must occur largely in the xylem.

Fig. 8. Radioautographs of cross sections of fruit, stem, and petiole of squash plant.—Fig. 8a. Exposure period 12 days.—Fig. 8b. Exposure period 30 hours.

Conceivably, the movement might result from a sucking of the solution directly into the xylem elements of the hydathodes at the margin of the submerged leaf. Efforts, however, to plug the hydathodes with glue or collodion before vacuum infiltration still failed to prevent rapid xylem transport.

The following experiment offers further evidence that scalding a portion of the stem does not impair xylem transport even though sieve tubes are plugged. Beginning 20 cm. behind the tip of a squash shoot, a 10-cm. portion of the stem was scalded in boiling water for one minute. The apical 10 cm. of the shoot was then carefully immersed in a 0.1 per cent solution of eosin in the suction bottle and subjected to vacuum infiltration, after which the bottle was removed. Thirty minutes later the eosin could be traced 40 cm. below the shoot tip, having completely traversed the 10 cm. scalded portion of the stem. In a second shoot, not scalded but otherwise treated identically, the eosin could be traced 35 cm. below the shoot tip. Accordingly, vacuum infiltration treatment was abandoned as a method of studying phloem transport exclusive of xylem transport. It may, however, prove useful for such studies if the plants are placed in a saturated atmosphere before treatment, as will soon be mentioned. It is also a valuable method where redistribution or nutritional effects are being studied.

EXPERIMENTS ON THE LOCALIZATION OF RADIOACTIVE PHOSPHORUS.—Figure 8a shows a radioautograph taken of various portions of a plant on which one leaf had been treated by vacuum infiltration eighteen hours before collection. In the axil of the treated leaf was a fruit, three sections of which appear faintly in figure 8a. In the largest of these sections the radioactive phosphorus has accumulated in the seeds. In the center of the top row of sections was placed a drop of phloem exudate. That it contained radioactive phosphorus is clearly shown by the radioautograph. Sections of the stem in figure 8a show localization of phosphorus not only in the vas-

cular bundles but apparently also at the periphery of the stem, at least in certain sections. Perhaps sufficient transpiration occurred from the stem during the experiment to carry the phosphorus solution to the surface and there concentrate it. The fruit sections show a similar phenomenon. Two of the stem sections in the third row from the top in figure 8a also show a line, in the approximate position of the interfascicular cambium, which connects adjacent bundles. This line, frequently found in radioautographs of stems, is believed to result from accumulation of radioactive phosphorus in the cells of the interfascicular cambium due to their relatively high metabolic activity, even though at this stage of development of the plant these cells are not actively dividing. In future experiments, in fact, radioautographs may provide the best means to obtain indications of the relative metabolic activity of various tissues of an organ by their accumulative capacity for radioactive elements. The fact that the developing embryo within an ovule is often quite distinct in radioautographs and that the ovule itself is distinct from surrounding tissue offers further evidence for the possibility of this type of research.

A comparison of figures 8a and 8b shows how length of exposure period affects clarity and intensity of radioautographs. Serial sections of each piece of plant material to be radioautographed were cut to a uniform thickness of 200 microns, and alternate sections were used in making the two radioautographs. Identical developing and printing procedure also was followed insofar as possible. P^{32} has a half life of about two weeks. Though a saturation effect is undoubtedly involved, a greater difference in the intensity of these two radioautographs might have been anticipated; 8a received nearly ten times as long an exposure period as 8b.

The same tendency is shown by figures 9a (eleven days' exposure) and 9b (four days' exposure), similarly prepared from a plant on which one leaf had been treated with radiophosphorus solution in a

Fig. 9. Radioautographs of stem cross sections from plants injected with radiophosphorus by vacuum infiltration.—Fig. 9a. Exposure period 11 days.—Fig. 9b. Exposure period 4 days.

plasticine well, two days before collection. Both figures show tendencies for localization of P^{32} in both internal and external phloem of the bicollateral vascular bundles and in the interfascicular cambium. Here there is even less difference in intensity of the two radioautographs, though one was exposed nearly three times as long as the other. Apparently most of the exposure is effected in the first few hours following the collection. Further evidence is the fact that if some of the sections cut from a squash stem containing radiophosphorus are placed over x-ray film immediately after cutting, whereas other serial sections from it are not placed over x-ray film until twenty-four hours later, the former radioautographs are as intense after one day's exposure as are the latter after about eight days, according to the results of one experiment. The relative importance of these first few hours of exposure, though somewhat variable, is usually much greater than can be explained simply by the decreasing radioactivity in the sections. Whatever the explanation, it is desirable in making radioautographs to begin exposure as soon as practicable after collection of the treated plant, as is shown by the experiments just described.

At the time the writer left for military service several other experiments were in progress. The indications of two of these experiments will be briefly mentioned to indicate the further possibilities of this type of research. These experiments should, however, be repeated and checked more fully.

1. If a radioactive phosphorus solution is carefully placed on a small portion of a cotton leaf within a plasticine well, the radioactive phosphorus will move down the stem to, but not beyond, a ring in which the bark is removed. This fact indicates that downward movement under these circumstances must be in the phloem only. Immediately above the ring, furthermore, radioactive phosphorus is found in the xylem as well as the phloem, as shown by radioautographs. This finding would seem to demonstrate that salts can diffuse radially from phloem to xylem, a fact indicated in early work of Mason and Maskell (1928), but not widely recognized.

2. In each of four squash plants a basal leaf was treated by vacuum infiltration at the time this leaf was guttating. In two of the plants the petiole of the treated leaf had been scalded before treatment, and in each case radioautographs showed that little or no radioactive phosphorus was exported from the leaf during the three hours after treatment, although the xylem of the petiole was not injured. In the other

two plants the petiole of the treated leaf was not scalded, and in each case very large amounts of radioactive phosphorus were exported from the leaf in a comparable period, presumably through the phloem. The vacuum infiltration method may thus prove the most promising means of treating leaves with radioactive phosphorus for the purpose of studying phloem transport, provided the plants are saturated before treatment.

In experiments designed to demonstrate whether or not materials can move simultaneously in opposite directions in the phloem, radioactive phosphorus carefully applied to leaves as herein described should serve as one useful indicator.

Recently, improved methods for directing or detecting viruses, thiamin, and certain other phloem-mobile materials should permit one of these to be used as a second tracer material for studies.

Thus Hildebrand (1942) and Hildebrand and Curtis (1942) have shown that virus movement in peach seedlings can be accelerated and directed by pruning, girdling, defoliation, or shading of parts of the growing seedlings, and that even mature leaves when shaded import the virus along with foods. Bonner (1942) has restricted thiamin movement in tomato plants by steam ringing the stem. He has shown that mature leaves apparently produce thiamin and export it along a carbohydrate gradient to growing parts of the plant where it may be accumulated. He found that the thiamin requirement of *Phycomyces Blakesleeanus* provided a satisfactory method for thiamin assay in the tomato plant.

With the use of radioactive isotopes in conjunction with other tracer materials, experiments relative to the mechanism of phloem transport will no doubt soon be performed to clarify many elusive points of this fundamental problem.

SUMMARY

Methods are described whereby the rapid longitudinal movement of radioactive phosphorus can be limited to the phloem and can be studied by means of radioautographs and the Geiger counter.

Studies on the rate and direction of transport and upon the localization of radioactive phosphorus under various conditions show that when this indicator is restricted to the phloem its movement is correlated with food movement in the plant.

CHROMOSOME NUMBER IN THE PROGENY OF TRIPLOID GLADIOLUS WITH SPECIAL REFERENCE TO THE CONTRIBUTION OF THE TRIPLOID¹

Robert E. Jones and Ronald Bamford

IN two previous reports (Bamford, 1935, 1941) concerning the chromosome number in *Gladiolus* and the relation of this factor to the hybridization of various species and varieties, one of the important objectives has been to determine the origin of the present-day commercial varieties which are tetraploids. That certain of the diploid species of this genus were concerned in the formation of these types has long been recognized (Beal, 1916); and, as McLean (1925) pointed out some time ago, certain characters in the commercial types must have come from the South African species. In terms of chromosome number, this means that certain characters of the commercial tetraploids have been derived from the South African diploid species. Whether this transfer was by means of amphidiploids, which might have been formed spontaneously after hybridization and then crossed again with other tetraploids, or whether triploids were involved, is still a question. In the first study (Bamford, 1935) it was apparent that triploids did occur among the commercial types and later it was shown (Bamford, 1941) that the probable origin of these was from either a diploid-tetraploid or the reciprocal cross, since over fifty per cent of such attempts were successful. Perhaps the most important observation in the recent study (Bamford, 1941), however, was that such triploids were partially fertile when used as the seed parent in further crosses with either of the original parents or with other diploid and tetraploid forms.

Although the thought still persists among many that triploids are sterile, an examination of the lit-

erature reveals that such is not always the case. Progeny have been produced frequently from triploids, especially when they were used as the seed parent in triploid-diploid crosses: in apple (Bergstrom, 1938; Nebel, 1933; Dermen, 1936), *Petunia* (Dermen, 1931), *Fragaria* (Yarnell, 1931), *Oenothera* (Capinpin, 1933), *Populus* (Bergstrom, 1940; Johnsson, 1940); *Tulipa* (Bamford *et al.*, 1939); Hall, 1937; Upcott and Philp, 1939), *Zea* (McClintock, 1929), *Allium* (Levan, 1933), *Datura* (Belling and Blakeslee, 1922; Satina *et al.*, 1938), *Lilium* (Satô, 1937), *Crepis* (Navashin, 1929), tomato (Lesley, 1928), potato (Perlova, 1940) and others. It has also been reported that progeny have been produced from triploid-tetraploid as well as from triploid-diploid crosses in *Petunia* (Dermen, 1931), *Phleum* (Nordenskiöld, 1941; Gregor and Sansome, 1930), and others. It would appear then that *Gladiolus* is not unusual in this respect.

Preliminary investigations (Leavenworth, 1938) showed that not only did these *Gladiolus* triploids, when used as the seed parents, behave in a fashion similar to those already reported in the literature (Bamford *et al.*, 1939; Dermen, 1936; Hall, 1937; McClintock, 1929; Navashin, 1929; Satina *et al.*, 1938; Upcott and Philp, 1939), but that some other type of chromosome behavior was taking place. Recently a similar series of observations has been made on the progeny of triploids in *Musa* (Cheesman and Dodds, 1942). This report presents the occurrence and frequency of these observations in *Gladiolus*.

MATERIALS AND METHODS.—With the exception of the previously reported triploid variety Charm (Bamford, 1935), the triploids used in this study were produced through reciprocal crosses between various tetraploid commercial varieties and diploid

species. Using the triploids as the female parent, seeds were obtained after crossing these with diploid species or some diploid hybrids, and also with tetraploid commercial varieties, as well as some tetraploid hybrids produced as the result of previous hybridization. Some examples illustrating the parentage of these progeny with their chromosome number are:

[Prof. Donders (60) \times *G. hirsutus* (30)] \times *G. tristis* (30)
 [*G. tristis* (30) \times Prof. Donders (60)] \times [*G. tristis* (30)
 \times *G. alatus* (30)]

[Miss Bloomington (60) \times *G. angustus* (30)] \times Dr. Moody (60)

[Prof. Donders (60) \times *G. tristis* (30)] \times [*G. primulinus* (60) \times Princeps (60)]

In all, approximately 500 plants were obtained, and of these it was possible to obtain chromosome counts from 460. It might be well to point out here that this latter group of plants is highly selective since nearly 5000 seeds were originally secured from such crosses.

All the work was done in the greenhouse during the winter months. Seeds from the triploids were gathered in the late spring and planted in pots the following fall. After one or two growing seasons or when the resulting corms were large enough, they were then planted in separate pots, and root tips were collected from each. These tips were fixed in Navashin's solution and prepared for sectioning by the short butyl alcohol method. Tissuemat was used for the embedding process, and all sections were cut 12 microns thick. Staining was accomplished by the crystal violet-iodine technique. Observations were made with the aid of a 90 \times , 1.3 apochromatic objective. All magnifications are listed with the plates.

In making the chromosome counts, it was impossible in a few cases to obtain a consistent number for some individuals. In recording these, it was necessary to list them as \pm the number which was found most frequently. The least inconsistent of these have been included in the tables, while the more variable ones were entirely eliminated from consideration.

RESULTS AND DISCUSSION.—It was presumed in all crosses that the diploid male parent contributed only fifteen chromosomes and the tetraploid male only

thirty chromosomes, because in all other crosses, such as diploid-diploid, tetraploid-diploid, and tetraploid-tetraploid, no irregularities in gametic chromosome contribution have been observed from an extensive study of the resultant hybrids.

After the chromosome number of the triploid progeny had been determined, the contribution of the triploid seed parent, when crossed with the diploid, was ascertained by subtracting the haploid number of the pollen parent. This is shown in table 1, while the contribution of the triploid, when crossed with the tetraploid as the pollen parent, is shown in table 2. In table 3 the total contribution in all cases is shown, thus combining the two previous ones, since the triploid parent was common to both types of crosses.

Throughout the course of the investigation, observations were made to determine whether certain triploids might have reacted differently when crossed with various diploids and tetraploids; but there was no indication of this in the behavior of any of the triploids in crosses with any one individual variety or species. For this reason, all triploid-diploid or triploid-tetraploid crosses were treated as a group rather than as individuals.

Triploid-diploid progeny.—It is quite obvious that there is a great variation in regard to the chromosome number (fig. 1-4) of the progeny. Plants with every complement from thirty-three to seventy-five chromosomes, with few exceptions, were observed one or more times. Despite this wide distribution and variation, it is possible to note that the majority of these plants are either triploids or tetraploids, the latter predominating.

In table 1, which shows the triploid contribution in the triploid-diploid crosses, it is obvious that the 3n/2 number of chromosomes, or approximately twenty-two to twenty-four, was contributed in only a small per cent of the cases. One might expect it to be that of greatest frequency in view of the results previously reported in some other plants. In *Tulipa* (n=12) Bamford *et al* (1939), Hall (1937), and Upcott and Philp (1939) have found that a triploid, when used as the female parent and crossed with a diploid, contributed from twelve to twenty-two chro-

diploid hybrids.

mosomes and in most cases from fifteen to eighteen, which would be about the $3n/2$ number. Nebel (1933) has shown in a $3n \times 2n$ cross in apple ($n=17$) that the chromosome number of the progeny ranged from thirty-five to forty-eight with the mode at 40.5, which would indicate that in most cases the triploid contribution would be somewhere near the $3n/2$ number. Capinpin (1933) in *Oenothera* ($n=7$) in a similar cross found the range to be fourteen to twenty-one with the mode at sixteen, which again approximates the $3n/2$ number from the triploid. Bergstrom (1940) and Johnsson (1940) in *Populus*, Dermen (1936) in apple and Levan (1933) in *Allium* all found similar results, with the progeny from $3n \times 2n$ crosses having somatic chromosome numbers ranging from the diploid to the triploid. In all these instances, however, practically all of the triploid progeny fell within this group. In *Gladiolus* it must be emphasized that such a contribution occurs in only a small proportion of the cases, and only a small portion of the progeny would have somatic chromosome numbers ranging from the diploid to the triploid. Within the group examined no diploids were found.

The second most obvious contribution of the triploid female in triploid-diploid hybrids of *Gladiolus* was that of thirty chromosomes, which would make the resulting progeny full triploids with regard to chromosome number. A few such progeny have been found by McClintock (1929) and Longley (1934) in *Zea*, Levan (1933) in *Allium*, and Satô (1937) in *Lilium* in crosses involving a triploid parent. Bergstrom (1940) in *Populus* and Dermen (1936) in apple, and more recently Cheesman and Dodds (1942) in *Musa*, have also found evidence of similar gametes from the triploid. Navashin (1929) in *Crepis*, in crossing a triploid F_1 *inter se* and with other sister diploid plants, found that approximately twenty-eight per cent of the progeny were triploids. This type of behavior is, therefore, not unusual in the case of triploids.

In *Gladiolus* the most common type of behavior seems to be the contribution of the full triploid number. This would mean that the progeny receiving this number would be tetraploid in nature. This is

not in general accord with the literature, although occasional tetraploid progeny from triploids have been reported. In *Solanum* (Perlova, 1940), *Tulipa* (Upcott and Philp, 1939), and *Populus* (Bergstrom, 1940; Johnsson, 1940) infrequent progeny have appeared with the full tetraploid chromosome number. However, Cheesman and Dodds (1942) in a recent report of *Musa* triploids, have emphasized that, when progeny are produced, the most vigorous ones are mostly tetraploids; that is, the triploid contribution is most frequent. This behavior in *Gladiolus* makes it possible to see that diploid characters would be transmitted to the tetraploids if this behavior has been common in the past development of commercial *Gladiolus*.

Triploid-tetraploid progeny.—Upon examining the chromosome number of the progeny (table 2) in the triploid-tetraploid crosses (fig. 5-8), it is obvious that the majority of them are either tetraploids or pentaploids. This indicates that the triploid, regardless of the pollen parent used, is consistent in the types of gametes most frequently produced. Cheesman and Dodds (1942) have expressed a comparable situation in *Musa*, "When diploid pollen is used instead of haploid, pentaploids occur in the progenies, and thirty-three chromosomes are again indicated as the most probable contribution from the female."

Twenty-four and thirty chromosome contributions have been made in these crosses in approximately the same proportions as in the triploid-diploid crosses, although the somatic chromosome number of the progeny are higher because of the thirty chromosome contribution from the pollen parent. Only a limited number of $3n \times 4n$ crosses have been previously reported; but Longley (1934) in *Zea*, Dermen (1931) in *Petunia*, and Gregor and Sansome (1930) in *Phleum* found that the triploid contributed approximately the diploid number when used in such a cross. The exception is the work of Cheesman and Dodds (1942) in *Musa*.

The full triploid somatic number was again contributed in most of the cases. This would indicate that the progeny receiving this contribution would be pentaploid. Dermen (1931) in *Petunia*, in a $3n$

\times 4n cross, found one plant with the full pentaploid number of chromosomes; and Nordenskiöld (1941), using *Phleum* in such a cross, found some of the progeny to be pentaploid. In neither of these cases, however, was the full triploid contribution a general feature of such a cross. This indicates that in *Gladiolus*, the triploid, regardless of the male parent, most

generally contributes the full triploid chromosome number. That this is the most frequent type of behavior is apparent from the fact that, out of 460 progeny observed (table 2), 129 had received such a contribution.

Instances of higher chromosome contribution than forty-five are also shown. This is comparable to the

results shown by Nordenskiöld (1941) in *Phleum*.

To explain the results presented above, it is only necessary to remember that failure of pairing, unequal divisions, lagging chromosomes, and the formation of restitution nuclei have repeatedly been described as characteristic of triploids. Stout (1932) in *Heimerocallis*, Capinpin (1933) in *Oenothera*, Dermen (1936) in the Baldwin apple, Levan (1933) in *Allium*, McClintock (1929) in *Zea*, Satina and Blakeslee (1937b) in *Datura*, Satô (1937) in *Lilium tigrinum*, Belling (1924) in *Hyacinthus*, Skovsted (1933) in cotton, and many others have observed these phenomena. Although no extensive observations have been made of the embryo sac behavior in triploid *Gladiolus*, those of Westfall (1940), Bellows (1941), and Satina and Blakeslee (1937b) in other genera demonstrate that the meiotic and subsequent divisions are similar to the PMC behavior so often described, although Jensen (1938) observed that they are not apt to show such violent irregularities. One of these phenomena, or combination of them, is all that is necessary to account for the variety and extent of chromosome numbers present in the female gametes produced by the triploid. The number twenty-four could be the result of nearly normal meiosis, while the number thirty would indicate the contribution of a diploid gamete, which is not uncommon in such hybrids. The numbers eighteen to twenty-three and twenty-five to twenty-seven, as well as those from twenty-eight to twenty-nine and thirty-one to thirty-five could have resulted from lagging of chromosomes or unequal division of chromosomes during the meiotic and subsequent divisions.

It is apparent that a frequent method of behavior in triploid *Gladiolus*, in contrast to that observed in other plants, is non-reduction or the formation of a restitution nucleus. This is also borne out by Darlington (1937), who states, "Nearly all triploids that have been examined, for example, form restitution nuclei whether they are the product of hybridization of two species or of self-fertilizing a diploid." This is not an uncommon behavior because it has been observed frequently in triploids and in other hybrids by Kostoff (1932) in *Triticum*, Crane and Darlington (1927) in *Rubus*, Andersson and Gairdner (1931) in *Dianthus*, Webber (1930) in *Nicotiana*, Lawrence (1936) in *Delphinium*, Graze (1935) in *Veronica*, and many others. However, the total range from thirty-six to fifty-five is due to other phenomena in addition to the formation of restitution nuclei. Lagging and unequal division of chromosomes after non-reduction could account for gametes with chromosome numbers from thirty-six to forty-four and from forty-six to fifty-five. It is also possible that lack of pairing, with the resultant irregular behavior of univalents, might produce a gamete with greater than the diploid or triploid number of chromosomes, as has been suggested by Karpechenko (1927). When those progeny receiving the numbers thirty-six to forty-four and forty-six to fifty-five are added to the 129 which received

the full forty-five chromosomes, it shows that over fifty per cent of all the progeny fell within the group which basically have resulted from the formation of restitution nuclei.

A fact which does not show up in the tabular material is that those plants of the triploid progeny with chromosome numbers from approximately thirty-three to forty-five are weak and in most cases have never flowered. It may be that the high mortality of apparently viable seeds, young seedlings, and even young corms in the first year of growth tends to eliminate these types so that the results here presented are the product of a selective process which may not represent a true picture of all the progeny but only those which are most vigorous. In a preliminary study of a few of these plants (Leavenworth, 1938) only a small percentage of the high polyploids was observed. Again Cheesman and Dodds (1942) in *Musa* have observed this same behavior. This means, of course, that the meiotic behavior of a triploid is a determining factor, but possibly not the only one, which accounts for the high percentage of polyploids, particularly the euploids found in this study.

From all this evidence of the presence of high chromosome numbers in the functional gametes of the triploids and the subsequent selection of the resulting plants, it seems entirely possible that the characteristics of the diploids may have been transmitted to the tetraploids through the medium of hybridization which involved the formation of triploid hybrids. Navashin (1929) has spoken of "... the tendency of triploids to produce polyploid interspecific hybrids ..." during his work on *Crepis*, and Crane (Huxley, 1940) in a recent article states, "We are often unable to say how a particular polyploid arose, but it is clear that the functioning of unreduced germ cells is a frequent method and that in conjunction with hybridization it has played an important part, both in nature and in cultivation, in the origin of new forms and species." *Gladiolus*, because of its extensive cultivation and hybridization, might well have followed this pattern.

Various irregularities in somatic cell division have been observed in the above-mentioned progeny (fig. 9-12). That these have involved tissues, as well as individual cells, is obvious, because in some cases certain areas in the root tips were found to have different chromosome numbers from those of the surrounding tissues. In one instance the epidermis within a limited area gave a consistent chromosome count of eighty-eight, while part of the cortex between that and the stele contained only seventy-five chromosomes. In another case the epidermis and cortex continually differed in number throughout the observable portion of the root. There were also instances of single cells which possessed chromosome numbers well over one hundred. In addition to these irregularities, a persistent nucleolus was found in some cells. The presence of such a nucleolus has previously been reported in *Gladio-*

lus (Mensinkai, 1939). Cases of premature division of the chromosomes at metaphase also were found. In such cases some of the chromosomes preceded the others to the poles. Observations of such mitotic irregularities have been made previously by Mensinkai (1939) in *Gladiolus*, Babu (1941) in groundnut, Stout and Susa (1929) in *Hemerocallis*, and others; but no special significance seems to have been attached to the phenomena. These irregularities may indicate a certain degree of unbalance, either in chromosome number or in the rhythm of cell division.

SUMMARY

Four hundred and sixty plants were obtained from several triploid *Gladiolus* ($3n = 45$), when these were used as seed parents in crosses with diploids and tetraploids. The somatic chromosome numbers of these progeny were determined in order to find the contribution of the triploid.

The range of the somatic chromosome numbers of the progeny extended from thirty-three to eighty-eight with the majority of those resulting from the triploid-diploid cross possessing sixty chromosomes, and most of those from a triploid-tetraploid cross possessing seventy-five.

The triploids contributed nearly every chromosome complement from eighteen to sixty. The majority of the triploid progeny fell into three main groups, the largest of which received from the triploid seed parent its full chromosome complement of forty-five.

This behavior could have come about through the formation of restitution nuclei during meiosis or subsequent divisions. This type of behavior is characteristic of triploids.

Such behavior in the triploid followed by hybridization offers one explanation for the transmission of characters from the diploid species to the tetraploid forms in *Gladiolus*.

The chromosome counts listed in this study are from root tips of plants which survived at least one year of growth, and no consideration is given to the possible chromosome number of those which failed to survive. The selective process of survival may possibly have been, therefore, an additional factor of importance.

Irregularities in mitotic cell division were observed in the root tips of several of the triploid progeny.

NICOTINE SYNTHESIS IN EXCISED TOBACCO ROOTS¹

Ray F. Dawson

EVIDENCE HAS recently accumulated which favors the view that the root organ is an important if not the sole seat of synthesis of certain of the vegetable alkaloids in those plants which produce them (Dawson, 1942; Dawson, 1942a; Krajevoj and Nechaev, 1941). This evidence has been obtained almost entirely through the use of reciprocal graft hybrids between species of different genera, some of which produce alkaloids and some of which do not. Subsequent chemical examinations then reveal the extent to which synthesis, translocation, and accumulation have occurred. The principal objection to this type of experimental approach lies in the fact that alkaloid synthesis is necessarily ascribed to the root system by inference, and that the process is not shown directly to occur in the roots as such. To complete the proof for the localization of the nicotine synthetic mechanism in the tobacco plant (Dawson, 1942a), therefore, excised roots of *Nicotiana tabacum* L. var. Turkish have been induced to grow in sterile culture so that their capacity for producing nicotine might be directly determined.

METHODS.—White (1938) has described the growth of the excised roots of two species of *Nicotiana* in sterile culture. For the purpose of the present investigation no systematic attempt has been made either to duplicate the conditions for growth prescribed by White or to ascertain the optimum environmental conditions for the growth of this particular strain of tobacco. Hence, the following description of methods of culture merely constitutes

a record of arbitrary procedures which we have followed in securing root growth sufficient to permit qualitative search for the presence of nicotine.

The basic nutrient medium possessed the following composition:

Ca(NO ₃) ₂ ·4H ₂ O	1.18	gm.
KNO ₃	0.52	gm.
MgSO ₄ ·7H ₂ O	0.46	gm.
KH ₂ PO ₄	0.136	gm.
Fe ₂ (SO ₄) ₃	8	mgm.
Sucrose	40	gm.
Extract of dried Brewer's yeast	100	ppm.
Redistilled water	2	liters

The most critical factor which we have encountered in controlling the growth of tobacco root tips under the conditions employed in this laboratory has been the temperature of the culture medium. Although no attempt has been made to determine the optimum temperature range and duration of exposure, it has been found that alternating periods of three to four days each at 24°C. and 37°C., respectively, give a rapid and sustained rate of growth. No other single factor appears to exercise so direct and immediate an influence upon the growth of these organs. Of considerable importance, also, to the growth of the roots is the presence of yeast extract. Unfortunately, the occurrence of pyridine compounds in yeast introduces a complication in studies of this type which we have been unable to avoid. The concentration of such substances in yeast, however, is so minute that the quantities of nicotine isolated

^a Decomposition point of the unrecrystallized dipicrates was in each case 218°C. (corr.).

could not possibly have been synthesized from this source alone.²

The presence or absence of nicotine in the root tissues and spent culture solutions was established qualitatively by examination of the picrates prepared from the steam distillates of these fractions. While quantitative methods of isolation were not employed, the procedures were so standardized that the dry weights of the crystals obtained may be considered as roughly indicative of the order of magnitude of the nicotine content of the various samples. The values given in table 1, therefore, represent minimum quantities and carry only general implications regarding the total amounts of nicotine actually synthesized by the roots during the successive culture periods.

RESULTS.—Nicotine was isolated in reasonably good yields from the roots and from the residual culture medium in all successive passages extending over a total period of ten months (table 1). It is remarkable that the bulk of the alkaloid occurred in all cases in the culture medium, while only very small amounts remained in the roots. The ability of the roots to synthesize nicotine was not lost with continued subculturing, nor was there a diminution in the amounts of nicotine dipicrate isolated from these passages such as to suggest merely a dilution of the quantity of alkaloid present in the original inoculum. Furthermore, when the cultures in one passage were subdivided into groups, and these harvested at different time intervals, it was possible to observe an

² Calculations based on data obtained by Melnick and Field (1940) indicate that the order of magnitude of the nicotinic acid content of dried yeast in the quantities used in this study would have been about 0.026 to 0.032 microgram per culture. Assuming that half the nicotine molecule might have been synthesized directly from the nicotinic acid of the dried yeast only about one-thousandth or less of the nicotine synthesized in the passage of April 22 to July 16 could be accounted for in this fashion.

increase in the yield of nicotine dipicrate with increase in the length of the culture period.

DISCUSSION.—The significance of these data with respect to the problem of the origin of nicotine in the tobacco plant lies in the fact that they provide the first evidence yet obtained for the synthesis of nicotine in detached plant organs under ordinary conditions of culture. Tobacco leaves and shoots when cultured in distilled water, salt solutions, or glucose solutions invariably cease to accumulate nicotine immediately after they have been excised from the plant, and a small alkaloid loss of about 10 per cent may be expected to occur. Similarly, it has been shown (Dawson, 1942) that the callous tissue which develops on the basal ends of excised segments of tobacco stalks during culture in a moist chamber does not accumulate nicotine, although mitosis and cell enlargement have both contributed to growth in this case. On the contrary, excised tobacco roots have here been shown to synthesize and to excrete nicotine in appreciable quantities during growth.

The excretion of nicotine by excised tobacco roots under these conditions raises a question of considerable interest. If such excretion occurs from the cut ends of the excised root tips in the form of xylem or phloem exudate, then the analogy between these results and those obtained with graft hybrids would indeed be highly suggestive. In such an event it becomes possible to suggest that nicotine may be manufactured in the meristems, perhaps, of the roots and from there may be *passively* translocated in a basipetal direction through either the xylem or phloem or both. After traversing such tissues in the stem and leaf it would eventually come to be deposited in large part in the spongy and palisade parenchyma of the leaf, while the water in which it had been carried would pass out of these cells to be lost by transpiration. In such an event one would expect to find nicotine occurring in the plant body wherever water

penetrates, and the amount of nicotine in any given organ or tissue would depend upon the average rate at which water had moved into that tissue or organ in response to transpirational losses and the length of time during which this movement had been maintained. Data already published concerning the distribution of nicotine in leaves (Dawson, 1942) and in stems (Dawson, 1942a) seem to provide a basis for such speculation.

Regardless of the correctness of such an interpretation it now seems clear that, of all the organs of the tobacco plant, only the root possesses an appreciable capacity for synthesizing nicotine, and that the presence of the alkaloid in tobacco leaves in greater concentrations than occur in either stalks or roots can now be ascribed primarily to translocation and accumulation.

SUMMARY

The ability of excised tobacco root tips to synthesize nicotine when grown in sterile culture has been investigated.

In contrast to all other organs of the tobacco plant the roots were found to manufacture nicotine in appreciable amounts as growth occurred.

A PROPOSED TAXONOMIC CHANGE IN THE TRIBE MAYDEAE (FAMILY GRAMINEAE)¹

R. G. Reeves and P. C. Mangelsdorf

THE ASSIGNMENT of generic rank to *Euchlaena* Schrad. as separate from *Zea* L. was made more than a hundred years ago, as a result of the study of external characters of the ear. Since that time, *Euchlaena mexicana* Schrad. has been the subject of much study from the points of view of various branches of biology, and many important facts showing its relationship to *Zea* now may be considered as established. Most of these facts were stated or reviewed in a recent publication by Mangelsdorf and Reeves (1939), and as a full review of them would be repetitious, they will be summarized only briefly here. *E. perennis* Hitchc. in some respects shows a greater departure from *Zea* than does *E. mexicana*, and in any comparison between the two genera, *E. mexicana* serves better. The statements to follow apply to *Euchlaena mexicana* but not all of them to *E. perennis*, and for that reason special characters of *E. perennis* will be discussed in the last paragraph.

In gross morphology, neither genus is known to have a character that is lacking in the other. Distichous ears, originally thought to be absent in *Zea*, have been reported in this genus by Tavečr (1935) and Langham (1940). Paired pistillate spikelets have been found by Reeves and Mangelsdorf (unpublished) to be of fairly regular occurrence in a form of *Euchlaena*. No real difference in response to length of day can be established when the various

The bulk of the nicotine thus produced was not retained within the root tissues but was excreted to the external medium where it accumulated.

These observations complete the proof for the localization of the nicotine synthetic mechanism in the root of the tobacco plant.

groups within the two genera are considered. Pod corn has disarticulation of the rachis and grains covered with bracts, in various degrees, in common with *Euchlaena*. Ordinarily the two genera differ in other characters but they have been believed to differ most sharply in those mentioned here.

Various morphological characters of the three genera of American Maydeae have been difficult to evaluate in the past. *Euchlaena* resembles *Tripsacum* L., a third genus, more than it does *Zea* in its disarticulating rachis, distichous spike, solitary pistillate spikelets, and covered grains. Writers of manuals have commonly subordinated these four characters to others, so as to indicate that *Euchlaena* is closely related to *Zea*; these characters have been used to separate *Euchlaena* from *Zea*. It is pertinent to ask, however, whether groups separated on the basis of these characters should necessarily be regarded as genera. It is significant that in respect to all four characters, intergrading forms between *Zea* and *Euchlaena* are known. Also, De Candolle (1882) has emphasized the error of classifying domesticated plants botanically on the basis of characters for which they are cultivated. These characters, or rather the opposite expressions of them, are precisely those for which *Zea* has been cultivated and selected.

In some regions where *Euchlaena* occurs naturally and comes into flower along with *Zea*, as in parts of Mexico, hybrid *Euchlaena*-like intergrades

¹ Received for publication August 6, 1942.

are more common than typical *Euchlaena*, and agriculturists find it necessary to renew their stock of maize every few years by securing pure seed, on account of continuous contamination. Collins (1921) observed this intergradation and accounted for the lack of the more maize-like forms in nature by their inability to survive, especially in competition with other plants. If agriculturists in these regions did not discriminate against the truly intermediate forms, or if these forms could survive in nature, *Zea* and *Euchlaena* no doubt would blend completely. Not only the intergrades occurring in these regions but probably also those reported by Taveār and Langham may be explained as hybrids, although the evidence of this in the latter two instances is less satisfactory. Assuming that this explanation is correct in all instances of intergradation between *Zea* and *Euchlaena*, opinion will vary as to whether the intergradation should be considered in taxonomic classification. For present purposes we need only to point out that numerous instances of intergradation between closely related species are known in which the intergrades have been well demonstrated to be of hybrid origin, and the *Zea-Euchlaena* intergrades agree quite satisfactorily with them. If we use any of the common criteria of species, such as distinctness or permanent isolation, we find that *Euchlaena* and *Zea* conform very well to closely related congeneric species.

The fact that hybrids can be produced between remotely classified groups like *Saccharum* and *Bambusa*, as reported by Venkatraman (1937, 1938), or like *Zea* and *Saccharum*, as reported by Janaki Ammal (1938), is of little or no importance in the *Zea-Euchlaena* problem. These remotely classified groups do not intergrade naturally, so far as reports show, and the fact that they can be hybridized artificially and even with great difficulty may indicate a fault in their present classification rather than a misconception concerning crossability in general. The necessity of interpreting crossability with caution is admitted, since certain genes, for example, may influence crossability. However, ample caution is believed to have been exercised in the present instance in respect to *Zea* and *Euchlaena*.

The two genera are as fertile, or nearly as fertile, with each other as they are with themselves, and this also applies to the F_1 and later hybrids between the genera. *Zea* and *Euchlaena* have the same chromosome number and their chromosomes are similar in morphology. Cross-over between their chromosomes is nearly normal. In so far as the gene loci have been determined, they are identical or nearly so in the two genera. The two genera are susceptible to many of the same insects and diseases. Although existing knowledge of the native range of each genus is incomplete, there is strong indication that both are natives of tropical America.

Hybridization should be mentioned again in connection with the probable origin of *Euchlaena* itself because the present writers (Mangelsdorf and Reeves, 1939) have advanced the hypothesis that

this genus originated as a hybrid between *Zea* and *Tripsacum*. Evidence in favor of this view is still being found, and nothing has been called to the writers' attention which is seriously contradictory to it. However, *Euchlaena* has not been completely demonstrated to be of hybrid origin, and there is diversity of scientific opinion on this question. The question is a peculiar one which may never lend itself to an undisputed conclusion. If *Euchlaena* should be definitely proven to be of hybrid origin, it ought still to be recognized as congeneric with *Zea*, at least if natural kinship be accepted as the main criterion. Evidence of hybrid origin is now on record for a great number of good taxonomic groups which were not formerly supposed to have originated in this manner. Phylogenetic development in general has occurred in various ways; in many groups it is convergent, in others its course is obscure. In actual practice, we find ourselves confronted with the question as to whether it is better to classify plant groups on the basis of their kinship in a broad sense, or to place the main emphasis on the mere mechanics of their origin, which is unknown for the majority of them. To make *Zea* and *Euchlaena* congeneric enables one to formulate the maximum number of prophesies and deductions and is more practical for the working taxonomist.

The close relationship between *Zea* and *Euchlaena* has been mentioned or implied in many scientific publications, only a few of which will be briefly mentioned here. Ascherson (1875) emphasized the similarity between *Euchlaena* and *Zea* and stated that *Euchlaena* appears to be merely a stunted type of *Zea*. East (1913) stated that the two groups are "simply diverse types of the same polymorphic aggregation, although they may be called species [not genera] if one desires." Many other scientific workers have implied in various ways that the difference between *Zea* and *Euchlaena* is not generic. This opinion has been expressed more recently by Langham (1938) and Beadle (1939).

Tripsacum shows very few indications of relationship to *Zea* and *Euchlaena* such as these show to each other. It can be hybridized with both *Zea* and *Euchlaena*, but this is done only with great difficulty and the hybrids are highly sterile. In these hybrids only about three pairs of chromosomes synapse and the synopsis is irregular and especially weak.

When all relevant facts known to us are considered, the relationship of *Tripsacum* to *Zea* and *Euchlaena* does not seem to be inconsistent with that shown between many other genera in the grass family. However, the relationship between *Euchlaena* and *Zea* is of a totally different rank; it is much closer and should be regarded as specific. Whether it should be considered as really specific would be an easier question to justify, but two salient facts indicate an affirmative answer: (1) The two forms are readily distinguishable by external, gross morphology. (2) Hybrid intergrades are of common occurrence only in certain localities; thus a barrier between the two forms is established.

It is therefore appropriate to propose a revision making *Zea* and *Euchlaena* congeneric. Since the name *Zea* L. was proposed prior to *Euchlaena* Schrad., the International Rules require that it be retained.

A transfer of two species into the genus *Zea* enlarges its scope, and a brief description indicating its new limits is therefore given.

ZEAL.—Staminate spikelets usually on terminal inflorescences, in sets of 2 or 3, 2-flowered, one spikelet of each set sessile, the other pedicellate; glumes membranaceous, lemma and palea hyaline. Pistillate spikelets usually on lateral inflorescences; consisting of one fertile and one sterile floret, or the latter sometimes developed; caryopses naked or covered by bracts; on a polystichous or distichous rachis in pairs, or with one member of the pair rudimentary or obsolete. Pistillate spike covered by one or several husks or spathes. Styles long, single, unbranched or slightly branched, protruding from the husks at the apex of the inflorescence. Coarse annuals or perennials. Type species *Zea mays* L.

There is some doubt whether *Zea perennis*, a perennial, should be retained as specifically different from *Zea mexicana*, an annual, for several reasons. First, it has often been explained as a mere autotetraploid form of *Zea mexicana*, but there is little or no experimental evidence upon which to base such

an explanation. Second, it is known to be native to only one small, isolated locality. Third, it hybridizes with *Zea mexicana* very readily. However, many closely related, undisputed species hybridize with each other, and a more important question is whether the hybrid intergrades may occur in sufficient numbers to obscure the identity of the two forms. Information concerning the fertility of F_1 and subsequent generations is inconclusive, but the probability is that the sterility of such hybrids is high, since the F_1 generation would be triploid, and triploids usually show pronounced sterility. Since it has been considered to be a species until the present time and since we have insufficient reason to consider it otherwise, a proposal to change its rank to that of a variety would be premature. Such a change may be justified in the future; this depends upon the results of further studies.

ON THE DEVELOPMENT OF XYLARY ELEMENTS IN THE FIRST INTERNODE OF *AVENA* IN DARK AND LIGHT ¹

Richard H. Goodwin

THE FIRST internode of grass seedlings has been the subject of numerous recent investigations. Of particular interest has been the extreme sensitivity of this structure to radiant energy. It has been proven that very short and weak exposures to visible light will check the elongation of this structure in completely etiolated plants. Histological studies by Avery, Burkholder and Creighton (1937) and by Araki (1939) have shown that in *Avena* both

It is well known that the formation and subsequent lignification of the secondary walls of vascular elements place certain mechanical limitations upon the potential growth of these elements and, hence, upon the tissues within which they are differentiated, at least in those cases where the tissues remain intact. It should be of interest, therefore, to investigate the nature of the relationship between vascular development and elongation in the internodes of etiolated and light-inhibited *Avena* seedlings. The results of such an analysis are presented in this paper. It is shown that radiant energy produces profound alterations in the rate of formation of vascular elements with reticulate and pitted secondary walls. The bearing of these changes on the mechanism of the light inhibition is discussed.

MATERIALS AND METHODS.—The plants used in the present study were from the same source and were grown under the same culture conditions as described in a previous paper (Goodwin, 1941). "Victory oats (from Svalöf, Sweden) were husked, and large seeds were selected. These were thoroughly wet with distilled water and then laid out, groove down, at an angle of about 60° in glass dishes on wads of absorbent cotton soaked with distilled water The dishes were placed in completely dark chambers within five minutes of wetting. The chambers, of 16 cu. ft. capacity, were air conditioned at 25° ± 0.5°C. and 80 per cent relative humidity. The air in the chambers was turned over at a rate of twice a minute and fresh air was introduced at the rate of 3 cu. ft. per minute."

Irradiations were made either with a beam of red light from a tungsten-filament Mazda ruby safe-light passed through a heat filter (a 6 cm. cell filled with ferrous ammonium sulfate, 81 g. Fe (SO₄)₂ (NH₄)₂ per 1. distilled water), the wave lengths thus obtained falling between 6000 Å and 8000 Å; or with white light from a battery of 40-watt 48-inch daylight Mazda fluorescent lamps, of which 93 per cent of the energy fell between 3800 Å and 7500 Å.

At suitable stages the plants were fixed and stored in formalin-acetic alcohol (5 cc. commercial formalin; 5 cc. glacial acetic acid; 90 cc. 50 per cent ethyl alcohol). After washing in water, most of the cortical parenchyma was removed with fine scalpels. Older plants were treated for one to four hours in Jeffrey's macerating fluid (a mixture of equal parts of 10 per cent chromic acid and 10 per cent nitric acid). The plants were then thoroughly washed and mounted in 70 per cent lactic acid which served both as a clearing agent and as a mounting medium (Simpson, 1930). Gentle pressure on the cover glass served to separate cells of the vascular bundles and to spread them out into a relatively thin layer without disturbing their positional relationships in the longitudinal direction. This method has two ad-

Fig. 1. The vascular anatomy of the first internode of *Avena sativa* (from Boyd and Avery, Botanical Gazette, 1936, fig. 4, reproduced through the courtesy of the University of Chicago Press).

the number and the length of the cortical parenchyma cells are reduced as a result of the light exposure. Goodwin (1941) has demonstrated that this inhibition is composed of two distinct phases: one, characterized by high sensitivity to radiant energy and correlated with the cessation of meristematic activity in the cortical parenchyma; the other, much less light-sensitive and correlated with a reduction in elongation of the cortical cells.

¹ Received for publication July 31, 1942.

vantages: first, the ease and speed with which mounts can be made; and second, the lack of damage to individual cells.

The vascular anatomy of the first internode of *Avena sativa* has been studied by Boyd and Avery (1936) and their reconstruction of the vascular system has been reproduced as figure 1. One unusual feature should be especially noted. The cotyledonary or scutellar bundle may be followed from its point of attachment to the axis at the cotyledonary or scutellar node upward, parallel to the central vascular complex, to the coleoptilar node where it bends back on itself and becomes a segment of the central vascular complex.

The nature and extent of vascular differentiation in the internodes of *Avena* seedlings of different ages grown in darkness and under two different light treatments were determined in cleared preparations. Counts were made of the numbers of the various types of tracheary elements present at three different levels in the internodes—the base (0.5 to 1 mm. above the scutellar node), the middle, and the tip (0.5 to 1 mm. below the coleoptilar node). These counts included the cells of the scutellar bundle and of the central vascular complex. The elements were grouped into the following categories depending upon the condition of their secondary walls: annular unstretched, annular stretched, spiral unstretched, spiral stretched, and pitted (including scalariform and reticulate).

Annular elements are elements which have secondary thickenings in the form of rings (fig. 2D). In the *Avena* internodes examined, these rings were found closely adjacent to one another in all elements in the earliest stages of development. Thickenings of this sort present no mechanical obstacle to stretching growth. During elongation, they may, by great expansion of the primary wall, become very widely separated (fig. 2E) before the collapse and complete rupture of the primary wall of the original cell. Elements in which the annular thickenings had been separated by a distance greater than the thickness of the rings were considered stretched.

Spiral elements are elements in which the secondary thickenings appear as spring-like spirals on the inside of the primary wall (fig. 2F). Here, as in the case of annular elements, the successive gyres of the spirals were always crowded very close together in the earliest developmental stages in all of the material examined. This type of element is also found in elongating structures, where the spiral thickenings become more or less pulled out (fig. 2G) or even perfectly straight in extreme cases. It seems probable that these spirals would tend to resist stretching growth to some extent, but even if this be true, the magnitude of such a force is unknown. Elements in which the successive gyres of the spiral thickenings were separated from one another by a distance greater than the thickness of the gyres were considered stretched. The complete array of intermediate types between annular and spiral elements (e.g. see fig. 2G) makes an accurate separation of

these two types difficult if not impossible, particularly in the cases where no stretching has taken place. Those elements which had their walls reinforced with intermittent spirals were arbitrarily classified as annular, since their walls should exhibit properties similar to those of annular elements at least where breaks occurred in the spiral thickenings.

Pitted elements are elements which have thickened secondary walls interrupted only by pits (fig. 2K). Once these secondary walls have become deposited they are no longer capable of longitudinal growth. Hence, pitted elements are not usually found in elongating structures. In the *Avena* internodes examined they were only found in regions which had completed their elongation. No evidence of tearing between these cells and the surrounding tissues was observed. Difficulty was experienced in distinguishing between pitted and unpitted elements due to the unbroken series of transitional types between annular and spiral elements on the one hand and advanced pitted types on the other (see Eames and MacDaniels, 1925, p. 92). Some of the stages in such a series are shown in figures 2 H, I, J, and 3 A, B, C, D, E. The first-formed cells of a transitional type are annular or spiral elements which show occasional narrow bands of secondary thickening connecting adjacent rings or successive gyres of a spiral (fig. 2 H and 3 A, B). Such cellulose bridges obviously impose limitations on the potential elongation of the element. For this reason walls which had an appreciable amount of bridging of this type were placed in the "pitted" category. Depending upon the extent and nature of the bridging of annular and spiral thickenings, scalariform or reticulate elements may be obtained.

RESULTS.—The results of this study will be considered under two headings: the sequence of xylary development in the internode; and the influence of light on this development.

Sequence of xylary development.—Table 1 gives a detailed sample of the basic data which are summarized in tables 2 and 3, and which are presented graphically in figures 5, 6, and 7. From an examination of these data the following conclusions may be drawn.

(1) For the first day and a half after germination annular elements are primarily differentiated. From one and a half to two and a half days, spiral elements are chiefly formed. Pitted elements are differentiated still later. This order of events is the one usually observed in the development of vascular bundles.

(2) Pitted elements are first formed at the base of the internode near the "nodal plate" of the scutellum when the plants are about two days old. A wave of differentiation surges up the internode from this basal region during the next three days. Successive stages in the development of pitted elements may be followed in a single plant in suitable vertical rows of cells. Near the scutellar node the walls may be considerably thickened, but as one passes upward, the secondary walls become thinner and thinner until the rows of tracheids or of vessel segments become

Plants grown in continuous white light ($4.92 \text{ ergs/mm.}^2/\text{sec.}$) after an initial dark period of two days (open circles). The arrow indicates the beginning of the light exposures.

light shown in B.—G. A stretched element showing annular and spiral thickenings in the same cell; from the dark-grown internode shown in A.—H. An annular unstretched element (above) and a reticulate element (below) from the middle of the internode grown in white light, shown in C.—I. An element showing thin strips of secondary wall connecting adjacent gyres of the original spiral thickenings; from the middle of a five-day-old, dark-grown internode.—J. A scalariform element showing the anastomosing structure of the wall thickening; from a five-day-old plant grown for the last three days in white light.—K. A pitted vessel showing portions of three vessel segments; from the same internode as J. Photomicrographs were made with a $45\times$ objective and a $5.5\times$ ampliplan eyepiece on metallographic plates. The preparations were the same as those used in making the cell counts summarized in table 2, and were unstained. Photomicrographs by Mr. R. J. Maas.

rows of undifferentiated, prospective xylary elements. The formation of pitted cells takes place almost exclusively in the central vascular complex and not in the scutellar bundle as is shown in table 4.

(3) A second center of vascular differentiation is clearly in evidence by the third day at the coleoptilar node of dark-grown plants and plants irradiated with red light, whence a second wave of differentiation passes downward through the internode. This second center is not in evidence in plants grown in white light, probably because it is masked by the upward wave of differentiation which overtakes the coleoptilar node twelve hours after the beginning of the light treatment.

(4) Elongation apparently takes place almost exclusively in those portions of the internode in which no pitted elements are visibly differentiated. It has been shown (Goodwin, 1941, table 2) that the total elongation taking place in dark-grown internodes between the second and the fifth days is distributed as follows: in the basal section, none; in the middle section, 22 per cent; in the apical section, 78 per cent. Table 2 shows that at the end of two days pitted elements are present in the basal portion of the internode where no elongation occurs. After three days pitting may be found half way up. The apical portion in which the greatest elongation takes place is the last to develop elements with pitted walls. Internodes which have pitted elements throughout their length (e.g., plants grown for half a day in white light) have completed their elongation. There is some evidence that the formation of elements with webbed-spiral and reticulate thickenings may begin

just before the cessation of elongation, since a few such elements were observed which gave the impression of having been somewhat stretched or pulled out (see fig. 3B, C). This indicates that the cessation of elongation and the commencement of development of pitted elements probably coincide.

It should be mentioned that losses in numbers of annular and spiral elements in the internodes of five-day-old plants are shown by tables 2 and 3 and figures 5, 6, and 7. These are probably only apparent losses for several reasons. The excessive stretching of annular elements results in the wide separation of the annular thickenings and makes an accurate count of all of these cells impossible. Some of the spiral elements before the loss of their protoplasts are apparently converted into pitted types by a subsequent webbing of the spirals (see fig. 2F). Lastly, the large numbers of pitted elements present at these later developmental stages tend to obscure the smaller and less conspicuous annular and spiral elements.

Effect of light on development.—An examination of figure 4 and a comparison of figures 5, 6, and 7 will show in a graphic way how radiant energy inhibits the growth of etiolated internodes and at the same time modifies vascular differentiation. The pattern of development is much the same for etiolated and for irradiated plants. The difference is clearly in the rate of formation of the cells of the different types. This is brought out in table 3. Exposure to light induces a significant increase throughout the length of the internode in the number of spiral elements over dark-grown plants (see table 3, column 5; and compare fig. 2A with fig. 2B and 2C). Even more significant is the increase in number of pitted elements and their distribution. In dark-grown plants pitted elements are present only at the base of the internode after two and a half days. Plants of the same age irradiated with red light have pitted elements present more than half the way up the internode in three out of five cases; and plants irradiated with white light have pitted elements present from the base to the tip in three out of five cases and beyond the middle in all cases (see table 1). Since most of the differentiation of annular elements is completed by the beginning of the irradiations, it is not surprising that their formation is unaffected by the light exposures.

DISCUSSION.—Protoxylem and metaxylem defined.

—The present investigation has dealt chiefly with the development of the primary xylem. Plant anatomists usually make a distinction between those xylary elements first formed within a structure (protoxylem) and those matured later on (metaxylem). Since developmental processes frequently do not present sharp discontinuities, but rather grade into one another by imperceptible degrees, the precise definition of morphological terms, such as protoxylem and metaxylem, which have a developmental significance, becomes a perplexing problem. It must be remembered that even though arbitrary definitions for such terms be accepted, the morphological boundaries of the regions or structures so described

will frequently be difficult or impossible to determine (see Frey-Wyssling, 1940).

Russow (1872) first employed the term *protoxylem* to describe the first-formed xylary elements of the primary body which are usually characterized by relatively small diameter, annular or spiral thickenings, and characteristic position within the plant. The development and modifications of the concept of protoxylem and of the companion term *metaxylem* are ably discussed by Bugnon (1924), who comes to the conclusion that the only method of distinguishing between protoxylem and the later-formed metaxylem is by the larger diameter of the metaxylem elements, regardless of the nature of the thickenings of the walls. He points out, however, that in those cases in which the elements of the primary xylem are all of the same size, no such distinction can be made. The International Association of Wood Anatomists' Committee on Nomenclature (1933) has defined protoxylem as "first-formed primary xylem, with tracheary elements characterized by annular or spiral thickenings," and metaxylem as "later-formed primary xylem, with pitted tracheary elements."

Frey-Wyssling (1940) has criticized and discarded these static definitions and has emphasized that a satisfactory distinction between protoxylem and metaxylem can only be made on a developmental basis.² He defines protoxylem as primary xylem which differentiates before elongation is completed and which becomes torn (or at least somewhat stretched) during this elongation; and metaxylem as primary xylem which arises at or after the close of elongation and which remains uninjured (and unstretched) and, therefore, probably also capable of functioning.³ These terms are used in this sense in the present paper, in figures 5, 6, and 7.

According to these definitions all of the xylem differentiated in elongating regions must be protoxylem, although no morphological criteria can be used to determine the nature of newly-formed unstretched elements in fixed material. In structures which have completed their elongation, however, an examination of the primary xylem in longitudinal aspect⁴ should permit a delimitation of the protoxylem—those cells which have become stretched subsequent to the deposition of their secondary walls. At least in the *Avena* internode, the annular and spiral thickenings of very immature xylary elements, the secondary walls of which were so thin as to be only faintly visible, were always found to be crowded very close together. Hence, elements with

² See also Eames and MacDaniels (1925, pp. 89–95), and Jeffrey (1917, p. 18).

³ "Das Protoxylem ist primäres Xylem, das vor dem Streckungswachstum differenziert und während der Stengelstreckung zerrissen wird. Das Metaxylem ist primäres Xylem, das während oder nach Abschluss des Streckungswachstums entsteht; es bleibt unversehrt und somit wohl auch funktionsfähig." (Frey-Wyssling, 1940). The two phrases in parentheses are my own amplification of these definitions.

⁴ The precise protoxylem-metaxylem boundary cannot always be determined in cross section.

their annular or spiral thickenings separated to any appreciable extent were considered stretched.⁵ It should be clear, then, that on this basis protoxylem and metaxylem can be distinguished not by the types of elements present (spiral or annular), but rather by the condition of the cell walls (stretched or unstretched). Xylary elements with pitted secondary walls are incapable of undergoing stretching growth

cessation of elongation of a structure on the one hand and the development of pitted vascular elements on the other. Let us review the evidence in favor of such a correlation in the case of the first internode of *Avena*.

Internodes still capable of elongation possess at least a short growing zone in which no pitted elements are found, and conversely, all internodes

FIG. 5

FIG. 6

FIG. 7

Fig. 5-7. Three dimensional graphs showing the relationships between length of internode, number and type of vascular elements at various levels, and time (data from table 2). Protoxylem elements (elements with stretched secondary walls) are indicated by stippling; unpitted metaxylem elements are indicated by single cross-hatching; pitted metaxylem elements are indicated by double cross-hatching. The fate of unstretched spiral and annular elements not associated with pitted elements is undetermined. They are left unshaded since they may become stretched into protoxylem or may remain unstretched as metaxylem. For a discussion of protoxylem and metaxylem, see page 822.—Fig. 5. Plants grown in total darkness.—Fig. 6. Plants grown in total darkness except for a five-minute exposure to red light ($0.17 \text{ erg/mm.}^2/\text{sec.}$) two days after germination. Note the light inhibition of length, the increase in total number of xylary elements, the increase in number of pitted elements, and their absence from the narrow zone in which most of the subsequent elongation takes place near the tips of the seventy-four-hour-old internodes.—Fig. 7. Plants grown in continuous white light ($4.92 \text{ ergs/mm.}^2/\text{sec.}$) after an initial dark period of two days. Note the complete inhibition of elongation, the still greater increase in number of pitted elements, and their distribution throughout the entire length of the internode only twelve hours after the beginning of the light exposure.

and must, therefore, be part of the metaxylem. The presence of such elements within a structure is an indication that no further elongation is taking place.

Correlation between elongation and vascular development.—It is clear from the observations of Nathansohn (1898), Stover (1924), Frey-Wyssling (1940), and others, as well as from those described in the present paper, that a correlation, much too close to be accidental, frequently exists between the

which have a continuous sequence of pitted elements from base to tip have completed their elongation. Furthermore, pronounced increases in the extent of pitted differentiation are visible within twelve hours of the beginning of light exposures known to inhibit elongation. The first of these changes must take place in a much shorter time interval. The presence of a few somewhat stretched "pitted" elements is evidence for the simultaneous development of such elements and the cessation of stretching growth.

Nathansohn (1898) has suggested three possible ways in which the cessation of elongation and pitted secondary wall formation might be related. First,

⁵ The general usefulness of this criterion for the delimitation of protoxylem and metaxylem will depend upon whether or not stretched and unstretched elements can be readily distinguished in most other vascular plants.

pitted vascular elements, the mature lignified walls of which are incapable of elongating, might mechanically limit the elongation of the structure. Second, cessation of elongation might occur first, thereby permitting the formation of rigid secondary walls. These first two possibilities need only be considered in those cases in which a close correlation between the two processes exists. Third, the physiological condition of the structure might initiate the two processes independently and either simultaneously or at different times. If simultaneously, it becomes extremely difficult to distinguish between this and the first two possibilities; if at different times, then cessation of elongation must precede the formation of pitted elements; otherwise the pitted elements would limit growth (the first alternative mentioned above). These relationships are indicated in table 5. Nathansohn presents evidence that the first two possibilities do not occur in certain instances, and on this basis he favors the third. It does not seem safe, however, to make generalizations for all plants from the scanty data at present available.

In the case of the first internode of *Avena*, no one of these alternatives can be selected to the exclusion of the others. Indeed, the environmental conditions might determine which of them apply at any given time. A few further facts should perhaps be considered. If xylary elements actually impose a mechanical limitation on elongation, then tensions might be expected to occur between these cells and the other tissues of the organ involved. Such tensions were not observed in the first internodes of *Avena*. When the parenchyma on one side of three-day-old plants, which were exposed to white light

for the last twenty-four hours, was pared away with a razor, no bendings of the remaining internode were observed. This evidence can be advanced as an argument against the view that pitted elements mechanically limit growth, but more extensive experiments of this sort need to be done.

The recent studies of K. and M. Wuhrmann-Meyer (1939) have shown that in the *Avena* coleoptile the walls of the parenchyma cells become progressively thickened with age, and that the cellulose fibrils of such thickenings are oriented more or less parallel to the long axis of the cells. They suggest that this may be responsible for the so-called "aging" or loss of plasticity of the coleoptile. Such secondary thickening of parenchyma walls might well have a mechanical retarding influence on elongation, such as that postulated for pitted vascular elements, and might provide a mechanism for checking elongation even in structures in which no development of pitted elements occurs. The author has observed that the walls of the parenchyma cells of *Avena* internodes become considerably thickened with age and it is possible that this process may contribute toward the limitation of elongation in the internode. If so, the tensions between the cortical parenchyma and the vascular tissues mentioned in the preceding paragraph may not occur.

Auxin is a factor which has not been studied in the present investigation, but which has a bearing upon the problem of growth in length. This group of substances has been shown to increase the plasticity of the cell wall and hence to promote cell enlargement when present in suitable concentrations. As many plant organs mature, the amount of auxin decreases,

TABLE 1. The number of xylary elements differentiated at 3 different levels in first internodes of *Avena*. Each vertical column gives the data for a single plant. These data are summarized in columns 3, 4, 7 and 10 of table 2.

^a Data for individual plants are given in table 1.

^b Only two of these plants had pitted elements within one mm. of the tip of the internode. In these cases no pitted elements were present at a distance of two mm. from the tip. It will be noticed that the internodes of these plants could have been expected approximately to double their length.

TABLE 3. The average number of annular, spiral and pitted xylary elements in the internodes of dark-grown plants compared with that of plants irradiated with red and white light. Data are taken from table 2.

and this may produce a physiological condition unfavorable to growth even before the cell walls have become appreciably thickened.

Numerous previous physiological investigations on the growth of the first internode of *Avena* have completely disregarded the vascular system. In the present study the close correlation between cessation of elongation and the development of pitted xylary elements has been emphasized. In the writer's opinion the possible rôle of the xylem in limiting elongation should be given serious consideration and further study.

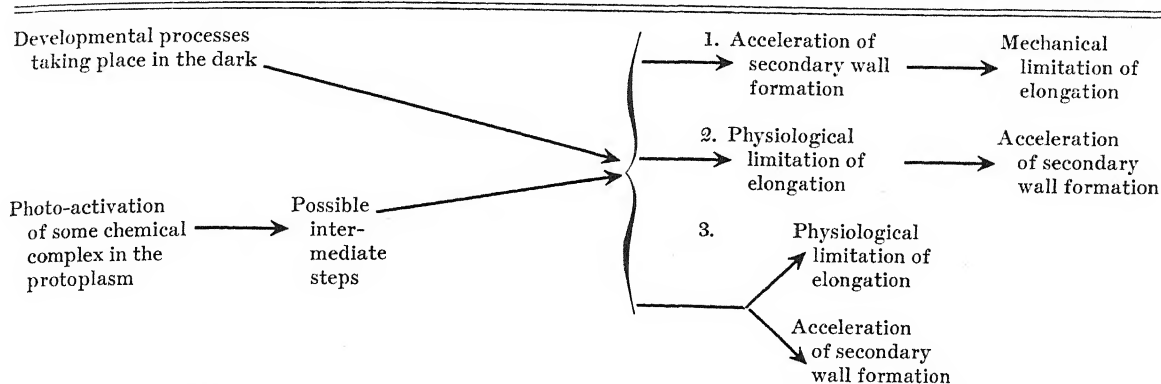

Effect of light on vascular development.—The retarding influence of light on the elongation of plants is too well known to require any amplification here. Little has been published, however, on the influence of light on the vascular system. The recent work of Smith and Kersten (1941, 1942) has shown that soft x-radiation will bring about a strong inhibition of the elongation of *Vicia* roots; and that this inhibition is closely correlated with the forma-

tion of pitted elements in the procambial strands much closer to the apical meristem than is normally

the case. In addition, other abnormal anatomical features are induced by this rather drastic treatment.

The visible irradiations used in the present investigation, on the other hand, are similar to those experienced by seedlings in the course of their natural development, and yet their effect in accelerating vascular differentiation and particularly the development of pitted elements is very marked. Whether the same phenomena are in operation here as in the case reported by Smith and Kersten is not known. The bearing of pitted secondary walls on the problem of elongation has already been discussed. The relation between growth in length and the inhibition of this process by light is obvious.

K. and M. Wuhrmann-Meyer (1939) have demonstrated that the secondary thickening of the parenchyma walls of *Avena* coleoptiles is hastened by light exposures which retard the elongation of this structure. This appears to be a developmental response very similar to that exhibited by the vascular elements of the *Avena* internode, and it is probable that the parenchyma of the internode is also affected in the same way.

The relationship between radiant energy and the two developmental processes under consideration is indicated in table 5. Secondary wall formation and the ultimate cessation of elongation both occur in complete darkness, but both of these processes are accelerated by exposure to radiant energy. The mechanism of this acceleration remains obscure.

In a previous paper (Goodwin, 1941) it was pointed out that if growth inhibitions of the first

internode at the lowest light intensities were due to inactivation of auxin by light, a very high efficiency in the utilization of the radiant energy would have to be postulated. It was concluded that some other mechanism was more probable at least at these low intensities although the possible rôle of auxin was by no means eliminated by this line of reasoning, particularly at higher light intensities.

SUMMARY

A study has been made of the development of vascular elements in the first internodes of *Avena* seedlings. Annular, spiral, and pitted elements are successively differentiated, and the presence of transitional types is emphasized. The first center of development of pitted elements arises at the scutellar node, and a wave of differentiation surges upward from this point through the internode. A second center occurs later at the coleoptilar node.

The rate of formation of spiral and particularly of pitted elements is greatly increased by exposures to visible light, pronounced effects being observed as early as twelve hours following weak irradiations. The close correlation between the light inhibition of elongation of the first internode and the formation of pitted xylary elements which are incapable of growth in length is brought out. The possible rôle of the xylem as an important cog in the light inhibition mechanism is discussed.

SPECIES DIFFERENCES WITH RESPECT TO WATER ABSORPTION AT LOW SOIL TEMPERATURES¹

Paul J. Kramer

IT WOULD be expected that plants native to warm climates and normally growing in warm soils would suffer a greater reduction in water intake when the soil is cooled than plants which normally grow in cooler soils. This opinion is supported by the results of one of the earliest investigations of the effects of cold soil on water absorption, that of Sachs (1875). He found that, under conditions of low transpiration, gourd and tobacco plants wilted at soil temperatures of 3° to 5°C., but they recovered when the soil was warmed to 12° or 18°C. Cabbage and turnips, on the contrary, remained unwilted even when the soil was cooled almost to freezing. Although a number of studies of the effects of cold soil on water absorption of individual species have been made, few direct comparisons of species, especially species from northern and southern habitats are available. The most extensive investigation is that of Döring (1935) who observed the reaction of fifty-seven species of European plants from various habitats and concluded that no clear relation exists between the distribution of plants and the effects of low temperature on their water absorption. Inspection of Döring's data indicates, however, that water intake by plants from northern flat moors and high moors was reduced less by cooling the soil than was water intake of forest trees and plants from warmer drier soils. No review of the literature will be made because the earlier work has been previously cited (Kramer, 1940) and the more recent investigations will be discussed later in this article.

This paper reports the results of an investigation of the effects of low temperatures on water absorption by several species not previously studied. Part of the experiments were specially planned to compare the behavior of species which normally grow in warm soil with that of species which normally grow at least part of the season in cold soil. Among the species compared were cotton (*Gossypium*

hirsutum L.) and watermelon (*Citrullus vulgaris* Schrad.), which thrive only in warm soil, and Georgia collards (*Brassica oleracea* var. *acephala* DC), which grow out-of-doors all winter and survive temperatures far below freezing. Among the woody species compared were loblolly pine (*Pinus taeda* L.) and slash pine (*P. caribaea* Morelet), which are natives of the southeastern part of the United States, and red pine (*P. resinosa* Ait.) and white pine (*P. strobus* L.), which have a more northern distribution. Other species not directly compared but for which data were obtained were privet (*Ligustrum japonicum* Thunb.), American elm (*Ulmus americana* L.) and sunflower (*Helianthus annuus* L.).

METHODS.—The herbaceous species were grown from seed in four or five quart metal containers while the woody species were transplanted into similar containers. The herbaceous species were usually about two months old and fifteen to eighteen inches high when used in experiments. The woody species were of about the same height, but of course much older, the loblolly and slash pine being over a year old and the red and white pine four or five years old. The elms were year-old seedlings, and the privets were from cuttings which were probably four or five years old. The pines had been out-of-doors during the winter prior to the time of the experiments.

The tops of the containers were covered with oil cloth during the actual experiments to prevent evaporation from the soil surface. The experiments were performed in two adjacent water baths located in a sunny part of the greenhouse. Six or eight containers were placed in each bath and kept at 25°C. for four or five days. The containers were weighed daily and the water lost by transpiration was replaced. Having established the relative transpiration rates of the groups in the two baths while both were at 25°C. the temperature in one bath was lowered about 5°C. each night while the temperature of the

¹ Received for publication August 14, 1942.

other or control bath was always kept at 25°C. The rate of transpiration of the cooled group was expressed as a percentage of the rate of the control group kept at 25°C. If the original ratio of cooled-control was not 100 per cent, each of the ratios obtained during the period of cooling was divided by the average ratio obtained during the four- or five-day period before cooling. For example, suppose the ratio of cooled: uncooled averaged .85 for the four- or five-day preliminary period during which both groups were kept at 25°C. As the soil temperature was then lowered, the ratios decreased to .60, .50, .20 and .10. Each of these ratios was divided by .85. In another experiment the ratio of cooled: uncooled might be 1.10. Then all ratios obtained during the cooling process would be divided by 1.10. This corrected all ratios to the same percentage basis, so that various species could be compared on the same graph. No control of the environment other than soil temperature was possible, but since the tops of all plants in any particular experiment were always exposed to the same environment any difference in transpiration between plants in cooled and uncooled soil may be assumed to result from decreased absorption in the cooled soil. This procedure is based on the assumption that absorption is approximately equal to transpiration. Such an assumption is not strictly true for short periods of time, especially if transpiration is rapid, but it is so nearly true for twenty-four-hour periods that the error is unimportant.

This method has certain limitations. It cannot be used on plants which are rapidly increasing in leaf area because low soil temperatures reduce the rate of growth of the cooled group as compared to the uncooled group, changing their relative leaf areas and rates of transpiration. The full effect of cooling the soil can only be observed when atmospheric conditions are favorable for high transpiration, so that

reliable data can only be obtained on sunny days. It was observed that the transpiration ratio cooled: uncooled was much higher on cloudy days than on bright days, indicating that the potential rate of transpiration does not exceed the rate of absorption from cold soil as much on cloudy days as on clear days. Bialoglowski (1936) observed that cooling the soil did not reduce night transpiration of lemons because the night rate at 25°C. was already lower than the day rate at freezing; hence the rate of absorption never became a limiting factor. The advantages of this method are that it eliminates the need for expensive environmental control apparatus and makes it unnecessary to pair the cooled and uncooled groups so that their transpiration rates are equal. This method also makes determinations of leaf areas unnecessary, saving labor, especially with conifers, and obviating the defoliation of the experimental plants at the conclusion of an experiment.

RESULTS AND DISCUSSION.—The data are summarized in table 1 and in figures 1 and 2. They are grouped in the table to show the actual comparisons made. The first three experiments were comparisons of collards and cotton, the fourth experiment was a comparison of collards with watermelon, while the fifth experiment was made on watermelon alone. All four species of pine were run simultaneously and the experiment was then repeated. Sunflower, elm, and privet were studied separately.

The most important data are those obtained by direct comparison of species. Inspection of table 1 and figure 1 shows that the behavior of Georgia collards is very different from that of cotton and watermelon. This difference appeared at a soil temperature of 15°C., and at 10°C. collards were absorbing about four times as much water as cotton and watermelons. Table 1 and figure 2 show that there is also a difference in the behavior of the northern and

southern species of pine. The absorption of water is reduced much more in the temperature range from 15°C. to freezing in loblolly and slash pine than in red and white pine which have more northern ranges. Kozłowski (1941) also found that water intake of loblolly pine was reduced more than that of white pine by cooling the soil, the difference being greatest at 5° to 10°C. Cooling the soil reduced water absorption of the broad-leaf evergreen privet less than absorption of the deciduous species, American elm. The reduction in absorption of sunflower is intermediate in magnitude between that of collards and that of cotton and watermelon, and within the

range of results reported by Clements and Martin (1934) for sunflower.

In general these data indicate some correlation between the reaction of a species to cooling of the soil and the temperature of the soil in which the species normally grows. Cotton and watermelons thrive only in warm soil while collards survive soil temperatures below freezing. All of the woody species studied, except possibly slash pine, grow in soils which are often frozen, at least at the surface, but the northern species have their roots in soil which is usually somewhat cooler than that in which the southern species grow.

These results support the work of other investigators. Duncan and Cooke (1932) reported that as the temperature was lowered from 28°C. to 10°C. the absorption of water by sugar cane plants was progressively decreased. Bialogłowski (1936) found that the day transpiration rate of lemon cuttings growing in nutrient solution in a constant environment chamber decreased as the solution was cooled below 25°C. or raised above 35°C. The transpiration rate of plants kept at 5°C. for two days was only 18 per cent of the rate at 25°C. Haas (1936) reported that the transpiration rate of lemon cuttings growing in soil increased as the temperature was increased from 19° to 31°C., but decreased at 35°C. The transpiration of grapefruit cuttings increased with increasing temperature from 19° to 27°C., but decreased from 31° to 35°C. Apparently such moderate soil temperatures as 15° to 20°C. measurably decrease water intake of citrus trees. Arndt (1937) found that cotton growing in a greenhouse wilted at soil temperatures of 17° to 20°C. and at solution culture temperatures of 10° to 18°C. The exact temperature of wilting seemed to depend on the rate of transpiration, wilting occurring at higher temperature when transpiration was rapid than when it was slow.

Brown (1939) found that water absorption by Bermuda grass was sufficiently retarded by cooling the soil to 10°C. to cause wilting, while Canada and Kentucky bluegrass were unaffected at this temperature. Schroeder (1939) discovered that extensive injury to the fall crop of greenhouse cucumbers is caused by a deficiency of water resulting from cold soil. Cucumbers apparently require a soil temperature higher than 20°C. to insure adequate water absorption and vigorous growth.

The data given in figure 1 and table 1 and the investigations just cited emphasize the fact that serious reduction in water intake is not limited to temperatures near freezing, but may occur in some species at temperatures between 10° and 20°C. It will be noted from figure 1 that watermelon absorbed only half as much water at 15°C. as at 25°C. Reduction in water intake at comparatively high temperatures was also reported for citrus fruits, cotton, cucumbers and sugar cane in the papers previously cited. Soil temperature has long been considered a factor of considerable ecological importance. It is now very properly receiving increasing attention as

Fig. 1-2.—Fig. 1 (above). Effects of soil temperature on absorption and transpiration of collards, cotton and watermelons.—Fig. 2 (below). Effects of soil temperature on absorption and transpiration of loblolly, slash, red, and white pine.

an important factor in the growth of cultivated plants both under field conditions and in greenhouses. Much winter injury is really injury from desiccation brought about by sun and wind causing excessive transpiration at times when the soil is frozen or so cold that absorption is too slow to replace the water lost in transpiration. Even the cooling of the soil resulting from a period of near-freezing weather or from watering greenhouse beds with cold water (Schroeder, 1939) may be sufficient to produce injury.

Not only the absorption of water, but the absorption of mineral salts and various internal physiological processes, are affected by soil temperature. Jones (1938) found that a troublesome chlorosis of gardenias occurs at soil temperatures of 18°C. or lower and disappears in warm soil. Furthermore, the rate of growth, size of leaves, and reproductive cycle of the plants were affected by soil temperature. Nightingale and Blake (1934) reported that Stayman Winesap apple trees in sand cultures at 45°F. were unable to translocate nitrogen from roots to shoots during a two-weeks experimental period. Batjer, Magness and Regeimbal (1939) found that young York Imperial apple trees with roots at 42° to 45°F. absorbed, assimilated, and translocated nitrogen after about four weeks. They suggested that Nightingale and Blake's trees might have done likewise if given sufficient time.

Brown (1939) found considerable differences in chemical composition and root and shoot growth of various species of grasses grown at low and high soil temperatures. Kentucky and Canada bluegrass made excellent root growth at a soil temperature of 50° or 60°F., while Bermuda grass made very little root growth. Root growth of Bermuda grass increased with each increase in temperature up to 100°F., but the bluegrasses were severely injured at this high temperature.

It is much easier to obtain evidence of species differences with respect to absorption than it is to explain why these differences exist. The writer has discussed the causes of decreased water absorption in a previous paper (Kramer, 1940). It was concluded that, while low soil temperature may hinder water absorption in several ways such as by reducing the water-supplying capacity of the soil, the rate of root extension, and the rate of active absorption, the principal cause of decreased water absorption at low temperatures probably is the increased resistance to water movement through the root cells. This increased resistance is caused in part by the increased viscosity of water as it is cooled and in part by decreased permeability of the root cells. It seems probable that there may be differences between species with respect to the changes in viscosity and per-

meability of the protoplasm caused by low temperature, just as there are species differences in respect to cold resistance. Levitt (1941) suggests that resistance to frost injury depends on the viscosity of the protoplasm being little increased and its permeability being little decreased by cooling. It may be that the protoplasm of cotton and watermelon undergo much greater changes in viscosity and permeability than the protoplasm of collards, thus resulting in a greater decrease in water absorption at low temperatures in cotton and watermelon than in collards.

The rate of cooling probably has considerable effect on the reaction to low temperature. Experiments with elm, privet and sunflower indicate that plants cooled to one or two degrees above freezing in four or five hours, or even over night, wilted severely, while plants cooled over a period of four or five days wilted but slightly. The rapidly cooled plants also transpired less than plants which were cooled slowly to the same temperature. Jones (1938) reported that gardenias which had been growing in warm soil wilted if suddenly cooled, but recovered their turgidity after a few days. It seems possible that slow cooling affords time for changes in protoplasmic properties to occur which tend to minimize the effects of cooling. This problem might be worth further investigation.

SUMMARY

An investigation was made of the effects of gradually cooling the soil on water absorption by collard, cotton, watermelon, sunflower, privet, elm, and red, white, loblolly and slash pine. Absorption was reduced in all species, but more in species which normally grow in warm soil than in species which normally grow at least part of the year in cold soil.

Watermelons and cotton absorbed only 20 per cent as much water at 10° as at 25°C., while Georgia collards absorbed 75 per cent as much at 10° as at 25°C. Loblolly and slash pine absorbed only 40 per cent as much water at 10° as at 25°C., while red and white pine absorbed 60 per cent as much at 10° as at 25°C.

The differences between species presumably result chiefly from differences with respect to the changes in viscosity and permeability of the protoplasm of the roots caused by low temperature.

Reduction in water absorption caused by cold soil is of considerable ecological and practical importance, because it often produces winter injury and even affects the growth of plants in greenhouses.

PREHISTORIC MAIZE FROM CAÑON DEL MUERTO¹

Edgar Anderson and Frederick D. Blanchard

FROM ALMOST the beginning of archeological exploration in the southwest there have been reports of prehistoric maize. Through the kindness of Dr. Clark Wissler of the American Museum of Natural History we were able to examine one of the largest of these collections, made by Earl H. Morris in 1923 in Mummy Cave, Cañon del Muerto, Arizona. There are about two bushels of ears in the collection. Having been stored in a stone cist with a tight cover they are practically free from rodent and insect attack and are incredibly well preserved. Aside from their generally dull color (to be discussed below) they look as though they might have been grown only a few years ago. Actually they are very ancient. Though many details remain to be worked out it is now possible to give approximate dates to such prehistoric remains in the Southwest (Roberts, 1935). Morris is of the opinion (personal communication) that this large cache of maize "dates either from Basket Maker II or III. There were no associated objects to make a closer period designation possible. I see no line of reasoning to suggest that the cache was made after A.D. 700 while the position and character of the cist in which it was found would make a date of A.D. 500 or somewhat earlier more plausible."

At the American Museum the ears were heaped pretty much at random in a large glass display case, and, since not all of them could be examined in the time at our disposal, we divided them into two approximately equal portions. From one of these (222 ears) we measured every ear with the exception of some very small nubbins. Row number was scored for each ear. The gross length and width of each ear and the width of the kernel were determined with a celluloid rule and are only approximate. Especially is this true for length, since there were a number of broken ears whose original length could

not be determined. For assistance in scoring the ears and for much pertinent information we are indebted to Dr. Marcus M. Rhoades of Columbia University.

As in many collections of Basket Maker maize there was a slight tendency to fasciated ears, four being so markedly flattened that they were recorded as "flat ears" (table 1), and the records made on them have not been used in computing averages. Since there were only four of these in over 200 ears their inclusion, however, would scarcely have changed the averages.

Three main colors were present; there were 105 red, 114 brown, and 11 mosaic ears. Both the red and brown varied somewhat in color, and we sorted each into two classes, but, while the division between the reds and the browns is fairly objective, deciding just where the dividing line shall come between light and dark brown or light and dark red is pretty much a matter of personal opinion.

The brown ears are a curious dull chestnut brown (raw sienna of Ridgeway), somewhat the color of acorns, and are quite different from modern maize. The color lies in the endosperm and is a general characteristic of Basket Maker maize, having been discussed by Collins in his report (1921) on the prehistoric corn submitted to him by Guernsey and Kidder. Collins decided that this color represents either a previously unknown genotype or that it is due to "slow disintegration." Knowing that many modern Indians parch their maize before storing it (Cushing, 1920, p. 265), we attempted to produce similar colors in our own stocks of modern Indian varieties by parching the ears in a gas oven. With a Papago yellow flour corn we were able to match the exact shade of the light brown prehistoric ears as shown in figure 1. The resemblance shown in this photograph would be even more striking if the reproduction were in color. While some of the discoloration may be due to age, it nevertheless seems

TABLE 1. Means and standard deviations for ear length, kernel width, and row number of maize from Cañon del Muerto, sorted according to color. It will be noted that the average differences are insignificant compared with the standard deviations.

	Number of flat ears	Number of specimens measured	Average ear length in cm.	Average width of kernel in mm.	Average number of rows
Deep red	1	50	10.9 ± 3.1	8.5 ± 1.0	12.2 ± 1.6
Red	0	51	12.2 ± 3.2	7.9 ± 0.9	12.2 ± 1.8
Mosaic	1	10	11.3 ± 2.4	8.7 ± 0.9	12.0 ± 1.8
Dark brown	1	41	11.8 ± 3.0	8.1 ± 0.7	12.9 ± 2.2
Light brown	1	67	11.1 ± 2.2	8.2 ± 1.0	12.0 ± 1.6
Total	4	222	11.4 ± 2.9	8.2 ± 1.0	12.3 ± 1.8

probable that its peculiarities of color are mainly due to its having been parched before it was stored. Part of the differences in color may be due to the severity of the parching; the rest is mainly caused by the differences in pericarp color. It is possible that the light brown originally had a white endo-

sperm, the dark browns a yellow endosperm. Both yellow and white endosperm are found today in the very similar maize grown by the Papago Indians.

According to Cushing, maize may be heated in three different ways before it is stored. It may be baked or steamed before it is completely mature (Cushing, loc. cit., p. 204-208) or it may be treated with dry heat after it is mature. "After the corn was ripened, two modes of making it eatable were extremely simple. Still on the ear it was toasted or in the kernel parched" (Cushing, loc. cit., p. 265). The maize from Cañon del Muerto had apparently been prepared in the second of these three ways. It does not have the translucent appearance of maize which has been steamed nor are the grains shrunken apart as when that process is employed. The grains have the dull appearance which can be matched by toasting mature maize with dry heat and some of the ears are slightly blistered along one side as if the heat had been too intense.

The variegated ears bore kernels similar to, if not identical with, those designated *mosaic pericarp* (P^{mo}) by Anderson and Ter Louw (1929). The red pericarp was apparently p^{rr} . In pericarp and endosperm color, the maize from this collection was practically identical with that discovered by Guernsey and Kidder and examined by Collins. While they did not report any mosaic ears the total number of ears in their collection was very small as compared with the more than 200 we have examined, and mosaic ears are known from other Basket Maker collections. In composition of the endosperm, however, the ears from Cañon del Muerto were quite different. All the material examined by Collins (1921, loc. cit.) was flinty, and, while we found a few flinty ears, they were very much in the minority. The change from flint to floury, however, though of great cultural importance, is genetically a relatively minor matter. As shown by Hayes and East (1915), it represents but a single gene difference, and it so greatly simplifies the preparation of corn meal that one would suppose it would immediately be selected in any variety of maize in which it arose, if climatic conditions permitted the cultivation of a flour corn. Because of the dominance relations between flinty and floury, the selection of a variety absolutely pure for floury would be a difficult matter, and it is not surprising that the flinty ears were encountered. In our

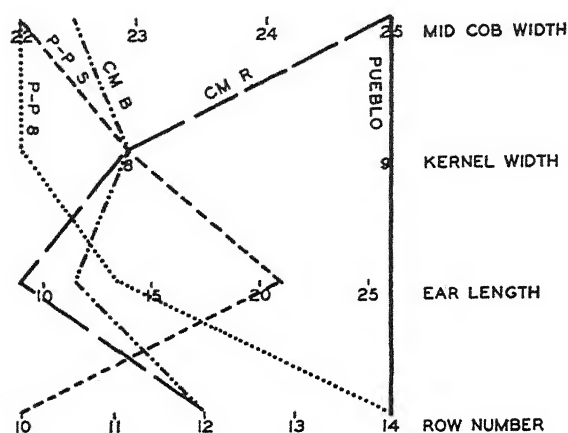

Fig. 2. Comparisons of prehistoric maize, modern Pima-Papago maize and modern Pueblo maize for four characters. Each line connects the average values for each character as follows: Pueblo. Unbroken line at right. Average values from Carter and Anderson collections of Pueblo maize.—Pima-Papago. (1) P-P 8—dotted line. Average values from Anderson's Papago inbred No. 8. (2) P-P S—short dashes. Average values from small-cobbed Pima-Papago varieties in Carter and Anderson collections.—Prehistoric. (1) CM R—long dashes. Averages of red ears from Cañon del Muerto. (2) CM B—dots and dashes. Averages of brown ears from Cañon del Muerto.

collections of the very similar flour corns grown by the modern Papago Indians, there are occasional ears with flinty kernels. The fact that the maize from Cañon del Muerto was prevailing flour corn suggests that it was culturally somewhat more recent than that described by Guernsey and Kidder (loc. cit.).

A single ear from the Cañon del Muerto collection has previously been identified as sweet corn by Erwin (1934). At the time of our visit it had been sent elsewhere and was not available for examina-

Fig. 3. Frequency distributions for kernel width in millimeters for the four color types.

tion. There were a few ears which at first sight looked as if they might be sweet corn, but closer examination showed them to be flint corn from which enough of the surface had cracked off to give it an irregular and translucent appearance not unlike that of sweet corn.

In its general appearance the maize from Cañon del Muerto is quite unlike that now being grown by the pueblo-dwelling Indians of the southwestern plateaus. Anderson and Cutler (1942) have recently discussed the races of maize in the southwest and have classified them into two main races, Pueblo and

Pima-Papago. While maize from Cañon del Muerto may not be identical with that now grown by the Papago and allied tribes, it is certainly very similar. Exact comparisons for four measured characters are presented in figure 2, and figure 1 shows photographs of each. It will be seen that for the four measured characters the differences between the modern Papago and the prehistoric maize are not greater than those between the two colors of the prehistoric maize. All of the prehistoric maize, however, shows differences from that grown by the modern Pueblo Indians.

We made a special effort to see if there was any

evidence for a dual origin of the maize from Cañon del Muerto. If either the red or the brown had been the original type and the other color had been introduced with a second type, other differences would for some time tend to accompany the color differences, even though the two types were allowed to cross. In the maize of the modern Pueblos, for instance, there seem to be significant average differences in row number and cob size between the white varieties and the dark red varieties in our collections. If there is any such average difference in the material from Cañon del Muerto the figures do not bear it out, as is shown in table 1, and figure 3. If the color varieties represented in the maize from Cañon del Muerto had separate origins, their original differences in row number and cob size and shape were too slight or had been too completely merged by crossing to be apparent statistically.

SUMMARY

Two hundred twenty-two ears of prehistoric maize from Cañon del Muerto, Arizona, were examined in detail. Although nearly 1500 years old, the material is in an excellent state of preservation.

The dull colors of the prehistoric maize can be reproduced in modern maize by dry heat, and it is concluded that this cache had probably been parched before being stored.

Most of the maize had floury endosperm, though a few ears were flinty. Pericarp was either red, colorless, or mosaic (P^{rr} , P^{mo} , or p).

In cob size, kernel size, kernel shape, etc., this prehistoric maize is unlike modern Pueblo maize and very similar to that now being grown by the Papago and allied tribes.

A statistical analysis of differences within and between the color varieties of the prehistoric maize leads to the conclusion that, as a whole, it was essentially homogeneous.

VITAMIN DEFICIENCIES OF CERATOSTOMELLA AND RELATED FUNGI¹

William J. Robbins and Roberta Ma

IN AN earlier paper (Robbins and Ma, 1942) we reported on the vitamin deficiencies of ten species of *Ceratostomella*. These species were found to suffer from partial or complete deficiencies for thiamine, for pyridoxine, for biotin or for two or more of these vitamins and were benefited by their addition to a basal medium. The present paper reports a survey of the vitamin deficiencies of thirteen additional species of *Ceratostomella* or related fungi.

MATERIAL AND METHODS.—The fungi investigated were received through the courtesy of the Division of Forest Pathology of the United States Department of Agriculture and were furnished by Dr. Ross W. Davidson who gave the following information on the cultures.

Ophiostoma catonianum G. Goid. This culture probably came from Goidanich.

Ceratostomella multiannulata Hedge. and David. Isolated from pine lumber in Louisiana.

Ceratostomella obscura David. Isolated from pine lumber in Louisiana.

Ceratostomella pilifera. Isolated from pine lumber in Louisiana.

Ceratostomella pluriannulata Hedge. Isolated from pine lumber in Louisiana in 1932.

Ceratostomella stenoceras Robak. This culture came from the Centraal Bureau voor Schimmel-cultures.

Ceratostomella microspora David.

Ceratostomella penicillata Grossman. Culture probably from Grossman in 1935 or 1936.

Grossmannia serpens G. Goid. Probably obtained from Goidanich.

Ceratostomella (Grossmannia) rostrocyndrica Davidson. Isolated from oak wood.

Endoconidiophora (Thielaviopsis) paradoxa.

Endoconidiophora coerulescens Munch. This culture originally came from the Centraal Bureau voor Schimmel-cultures.

Endoconidiophora adiposa (Butler) Davidson. Culture from sugar cane or water nut, series B-8 from Fred Andrus.

Dr. Davidson stated that none of these cultures was less than five or more than nine years old and some, for example *C. multiannulata*, had lost the ability to form perithecia.

¹ Received for publication August 24, 1942.

All cultures were tested for purity after being received, and those contaminated with bacteria were isolated in pure culture. No attempt, however, was made to prepare single spore isolations for the experiments reported in this paper. Stock cultures were maintained on a thiamine-peptone agar.²

² This is prepared by adding 625 m μ moles of thiamine and 1 g. of neopeptone per liter to the basal medium.

Each of these organisms was grown on agar slants in test tubes containing approximately 8 ml. of a basal medium, or the same medium to which thiamine, pyridoxine, biotin or all possible combinations of these vitamins were added. They were grown also on the basal medium plus Difco malt extract desiccated. In addition, those organisms which showed vitamin deficiencies were cultured in 25 ml. of the

Fig. 1. Growth of three fungi on a mineral-dextrose medium containing asparagine and purified agar supplemented as follows: (1) no additions; (2) thiamine; (3) pyridoxine; (4) biotin; (5) thiamine and pyridoxine; (6) thiamine and biotin; (7) pyridoxine and biotin; (8) all three vitamins. A, *Cerastostomella stenoceras*; B, *C. pluriannulata*; C, *Grossmannia serpens*. All forty days old.

basal liquid medium in 125 ml. Erlenmeyer flasks to which the vitamins or malt were added. All cultures were in triplicate and incubated at 20°C. in the dark. All inoculations were made by transferring a bit of mycelium the size of a pin head except for the liquid cultures of *C. stenoceras*, *C. microspora* and *E. paradoxa* where a drop of a spore suspension in distilled water was used.

The basal medium contained per liter, 50 g. dextrose, 1.5 g. KH_2PO_4 , 0.5 g. MgSO_4 , 7H₂O and 2 g. asparagine. To this solution the following trace elements in p.p.m. were added: 0.005 B, 0.02 Cu, 0.1 Fe, 0.01 Ga, 0.01 Mn, 0.01 Mo and 0.09 Zn. For the agar cultures 1.5 per cent purified agar³ was added to the basal medium.

The dextrose was Corn Products C.P., the asparagine was purified by treatment with Norit A and recrystallization from redistilled alcohol. All other chemicals were of C.P. grade. The thiamine and pyridoxine were Merck's synthetic; the biotin methyl ester was a crystalline product from the S.M.A. corporation. Dry weights of the mycelium in the liquid cultures were obtained by filtering the mycelium into a Gooch crucible, washing with distilled water and drying at 100°C.

EXPERIMENTS.—The thirteen fungi were grown on agar slants in triplicate on nine different media as follows: (1) the basal medium, and the basal medium plus, per tube, (2) thiamine 5 m μ moles, (3) pyridoxine 5 m μ moles, (4) biotin methyl ester 0.05 μ g., (5) thiamine and pyridoxine, (6) thiamine and biotin, (7) pyridoxine and biotin, (8) thiamine, pyridoxine and biotin, (9) 0.3 g. malt extract. Observations were made at intervals on relative growth, and no cultures were discarded until no further development could be observed. All were observed at inter-

³ The purified agar was prepared by extracting Difco agar with 5 per cent aqueous pyridine followed by 1 per cent hydrochloric acid. The agar was then neutralized with calcium hydroxide and washed free of excess calcium.

vals over a period of forty days and some for a considerably longer time.

Eleven of the thirteen fungi showed marked deficiencies on the agar media for one or more of the three vitamins and these were grown in liquid cultures as follows: (1) in the basal medium and in the basal medium plus, per flask containing 25 ml. of medium, (2) 10 m μ moles of thiamine, (3) 50 m μ moles of pyridoxine, (4) 0.1 μ g. biotin methyl ester, (5) thiamine and pyridoxine, (6) thiamine and biotin, (7) pyridoxine and biotin, (8) thiamine, pyridoxine and biotin and (9) 0.3 g. malt extract. Observations were made of relative growth in the liquid cultures and dry weights of the mycelium were determined after from seven to forty-seven days incubation. The results were as follows:

Ceratostomella stenoceras appeared to be a thiamine-deficient organism. By the end of forty days (fig. 1) a small amount of subsurface growth had developed in the tubes containing the basal medium and that supplemented with pyridoxine, with biotin, and with pyridoxine and biotin. The surface of the agar slants was covered with mycelium in tubes of the basal medium supplemented with thiamine, with thiamine and pyridoxine, with thiamine and biotin, and with all three vitamins. Little difference was noted in the rapidity of growth on any of the media containing thiamine which suggests that partial deficiencies for pyridoxine and biotin do not exist for this fungus. The growth on malt agar was about like that on the agars containing thiamine. Growth in the liquid cultures (table 1) confirmed that on the agar media except for the liquid medium containing malt extract.

Grosmannia serpens on both the agar medium and in the liquid medium showed a complete biotin deficiency (fig. 1 and table 1). It grew rapidly and within eight days had covered the surface of the agar slants on those media containing biotin. Growth on

malt agar or in the liquid medium containing malt was about the same as on the media containing vitamins.

Ceratostomella multiannulata appeared to suffer from a complete pyridoxine deficiency and a partial thiamine deficiency. The growth on the basal agar medium and on that supplemented with thiamine, with biotin, and with thiamine and biotin was scant

and colorless. More growth with a brownish color appeared on the pyridoxine medium and on that containing pyridoxine and biotin. Heavy growth covering the entire slant developed on the medium supplemented with thiamine and pyridoxine, and with all three vitamins (fig. 2). The growth on the malt agar was somewhat heavier than on the medium containing all three vitamins.

Fig. 2. Growth of three fungi on a mineral-dextrose medium containing asparagine and purified agar supplemented as follows: (1) no addition; (2) thiamine; (3) pyridoxine; (4) biotin; (5) thiamine and pyridoxine; (6) thiamine and biotin; (7) pyridoxine and biotin; (8) all three vitamins. D, *Ceratostomella multiannulata*; E, *C. penicillata*; F, *C. microspora*. All forty days old.

This organism grew slowly in liquid culture (table 1), and at the end of twelve days the maximum growth in the vitamin media was 18.4 mg. In the medium supplemented with malt it was 61.0 mg. which suggests that *C. multiannulata* has unidentified partial deficiencies. In general the growth in liquid culture was poorer than on agar. The dry weights taken at the end of twelve days (table 1) showed no benefit from the addition of pyridoxine, though this was evident on agar (fig. 2). Subcultures were made from the liquid cultures containing the basal medium and those supplemented with thiamine, with pyridoxine, and with biotin into similar solutions and allowed to grow forty-seven days. Although the growth was not great, the results (table 2) clearly showed benefit from pyridoxine.

0.1 μ g. biotin	0.0	0.2

Ceratostomella pluriannulata resembled *C. multiannulata* in its relation to thiamine, pyridoxine and biotin, except that it grew somewhat more rapidly than the latter organism (fig. 1). Its response in liquid culture in contrast to that on agar suggests a complete deficiency for both thiamine and pyridoxine (table 1). However, subcultures made from the basal medium and from those supplemented with thiamine, with pyridoxine, and with biotin, which were allowed to grow forty-seven days, showed a small effect from the addition of pyridoxine (table 2). This fungus like *C. multiannulata* evidently synthesizes a little thiamine though not enough for maximum growth. It is possible that its ability to synthesize thiamine may be conditioned by the oxygen supply, that is by whether it grows in liquid or on agar. This is suggested because it appeared to develop more extensively on the agar medium supplemented with pyridoxine than in the liquid medium which contained the same vitamin. *C. pluriannulata* and *C. multiannulata* both showed a strong response to malt suggesting partial unidentified deficiencies.

After fifty-three days mature perithecia discharging ascospores were observed on the agar medium supplemented with thiamine and pyridoxine, with all three vitamins and with malt. None was observed on the media supplemented with pyridoxine, or with pyridoxine and biotin. Although the fungus grew fairly well (fig. 2) on the media containing pyridoxine, or both pyridoxine and biotin, it apparently needed the presence of both pyridoxine and thia-

mine to permit growth sufficiently vigorous for the formation of perithecia.

Ceratostomella penicillata formed little mycelium on the basal agar medium and on that supplemented with thiamine, with pyridoxine or with thiamine and pyridoxine. The growth with biotin and with pyridoxine was somewhat better but still very scant. Growth on the medium with thiamine and biotin was good (fig. 2). Somewhat more rapid development was observed on the medium with all three vitamins and still better on the malt agar. On the agar media *C. penicillata* suffered from a complete or nearly complete deficiency for thiamine and biotin. This was confirmed by the growth in liquid cultures, though the dry matter produced even in eighteen days was small. It responded markedly to the malt extract in both the agar and liquid medium.

Ceratostomella microspora grew little on the basal agar medium or on that supplemented with thiamine, with pyridoxine, or with pyridoxine and thiamine. Slightly greater growth was observed on the medium to which biotin, or both thiamine and biotin were added and somewhat better growth with a little surface mycelium developed on the agar medium supplemented with pyridoxine and biotin. However, not until all three vitamins were added did much mycelium develop (fig. 2) and the growth on malt agar was considerably better. This fungus appeared to suffer from complete or nearly complete deficiencies for thiamine, pyridoxine and biotin and in addition from partial deficiencies for unidentified factors in malt. These conclusions were confirmed by the liquid cultures (table 1).

After eighty-seven days mature perithecia in considerable numbers were observed on the agar medium supplemented with all three vitamins. They were produced in a circle about 1.5 cm. in diameter with the point of inoculum as the center.

Endoconidiophora paradoxa grew very rapidly on the agar media containing thiamine. At the end of four days very little growth had appeared in the tubes containing the basal medium, or that supplemented with pyridoxine, with biotin, or with biotin and pyridoxine. In all others the surface of the slant was covered with a heavy black mycelium. This picture remained unchanged for more than thirty days during which the tubes were under observation (fig. 3).

The same results were obtained in liquid culture (table 1). About 200 mg. of mycelium (dry weight) were obtained in the cultures which contained thiamine, or thiamine and one or both of the other vitamins, and also in the malt medium. In the solutions lacking thiamine the maximum dry weight was 3.3 mg. *E. paradoxa* appeared to be a thiamine-deficient organism. Its growth on media containing malt was slightly better than on the media containing vitamins. Its rapid growth, large dry weight and general character suggests that it might be investigated further as a means of bio-assay for thiamine or its intermediates.

Ophiostoma catonianum on the agar medium appeared to suffer from a complete pyridoxine deficiency and a partial deficiency for thiamine. Its development during the first week or ten days was somewhat better on the medium containing pyridoxine and thiamine or all three vitamins than on that supplemented with pyridoxine alone. It grew a little better on malt agar than on agar containing the three vitamins. At the end of twenty-eight days the growth on the basal medium and on that supplemented with thiamine, with biotin, or with thiamine and biotin, was thin and waxy, 12 or 15 mm. in diameter. On all the media containing pyridoxine the growth was thick and cottony. The graphium stage was freely produced on the medium supplemented with thiamine and pyridoxine, with pyridoxine and biotin, and with all three vitamins, but formed scantily on the media containing pyridoxine or malt. The appearance of *O. catonianum* on the various agar media is shown in figure 3 at the end of eighteen days' incubation. Its appearance was essentially unchanged after forty days' incubation.

These results were substantiated in general by the growth in liquid culture (table 1). The cause for the poorer growth in the liquid medium containing malt as compared to that in the medium supplemented with all three vitamins was not investigated. The dry weights show the complete pyridoxine deficiency but do not furnish evidence for the partial thiamine deficiency observed on the agar cultures.

Ceratostomella pilifera showed on the agar media a complete biotin deficiency and perhaps partial deficiencies for thiamine and pyridoxine. During the first week or ten days little growth developed on the basal medium or on that supplemented with thiamine, with pyridoxine, or with thiamine and pyridoxine. The growth on the medium containing biotin was good; it was a little better on that supplemented with biotin and thiamine, with biotin and pyridoxine, and with all three vitamins. The growth on the malt agar was a little heavier than on any of the media supplemented with vitamins. At the end of twenty-eight days a scant growth of black rhizoid-like mycelium had developed in the basal agar medium and in that supplemented with thiamine, with pyridoxine, or with thiamine and pyridoxine. On the media supplemented with biotin, with biotin and thiamine, with biotin and pyridoxine, with all three vitamins, and with malt, the agar slants were covered with a thick gray cottony mycelium with a powdery surface growth (fig. 3).

In the liquid cultures little growth was obtained without the addition of biotin. However, a considerably greater (about three times greater) growth developed when thiamine or pyridoxine or both were present with the biotin. This suggested partial deficiencies for thiamine and for pyridoxine, the satisfaction of either of which resulted in a greater syn-

thesis of the other. We do not believe that this may be taken as evidence that pyridoxine replaces thiamine or vice versa. In contrast to the results on agar less growth was obtained in the liquid cultures containing malt than in those supplemented with vitamins. A different amount of malt might have given better results.

Ceratostomella obscura evidenced a complete deficiency for thiamine and biotin. By the end of twenty-eight days a delicate widely spreading mycelium had developed in the tubes containing the basal medium and those supplemented with thiamine, with pyridoxine, with biotin, with thiamine and pyridoxine, or with pyridoxine and biotin. This slight growth may have developed from the vitamin supplied with the inoculum. The surface of the agar slants on the tubes containing thiamine and biotin, and on those containing all three vitamins, was covered with a yellowish-brown waxy growth with little aerial mycelium. In the tubes containing malt extract the medium was covered with growth and considerable aerial mycelium had developed (fig. 3). The malt agar appeared to be somewhat superior to the vitamin medium. The growth in liquid culture (table 1) confirmed the observations made on the agar cultures. Growth in the liquid medium containing malt was markedly superior to that in the media containing vitamins.

Endoconidiophora adiposa grew rapidly on the basal agar medium. Within four days the agar slants were covered with a gray fluffy mycelium. Little effect of the addition of any one or all of the vitamins or of malt extract was noted.

Endoconidiophora coerulescens grew on the basal agar medium. Its development on the malt agar was more rapid. It appeared to show some response to thiamine but the thiamine deficiency was slight.

Ceratostomella (*Grosmannia*) *rostracylindrica* grew slowly on the basal agar medium. After two weeks the colonies were only 8 mm. in diameter and after thirty-four days they had increased to 15 mm. None of the vitamin additions had any effect, but the growth on malt agar was about twice that on the basal medium.

DISCUSSION.—Eleven of the thirteen fungi used in this investigation showed partial or complete deficiencies for one or more of the three vitamins, thiamine, pyridoxine and biotin (table 3). Four showed a complete or nearly complete deficiency for thiamine, six for pyridoxine, and four for biotin. In addition, partial deficiencies for thiamine were evidenced by five, and for pyridoxine by one. Two of the fungi had complete deficiencies for two of the vitamins and one for all three. In this investigation and the one reported earlier, species of *Ceratostomella* and related organisms have been found which evidence nearly all possible combinations of partial and complete deficiencies for thiamine, pyridoxine

Fig. 3. Growth of four fungi on a mineral-dextrose medium containing asparagine and purified agar supplemented as follows: (1) no addition; (2) thiamine; (3) pyridoxine; (4) biotin; (5) thiamine and pyridoxine; (6) thiamine and biotin; (7) pyridoxine and biotin; (8) all three vitamins. and biotin. The results emphasize the importance of these three vitamins as constituents of the medium for this group of fungi and explain why media containing natural supplements have been so freely and successfully used in their cultivation.

Little previous work on the vitamin deficiencies of these organisms has been reported. Hawker found that the addition of a lentil extract to a mineral-dextrose medium containing agar increased the production of pycnidia by *Ceratostomella adiposum*. The inositol-free extract was ineffective (Hawker, 1936).

Leonian and Lilly (1938) were unable to grow *Ceratostomella multiannulata* on a mineral-dextrose medium containing NH_4NO_3 and agar or on the same medium supplemented with thiamine, riboflavin, an amino-acid mixture or thiamine with amino-acids. Growth occurred when yeast extract was added to the agar medium, and they tentatively listed this fungus as a biotin-deficient organism (1940). Our results do not indicate a biotin deficiency for this fungus but a complete pyridoxine deficiency and partial thiamine deficiency.

In spite of the primary importance of the three vitamins mentioned for most of the fungi included in this study, it should be noted that some of them grew better on a malt agar than on the agars supplemented with vitamins. This suggests that these organisms may suffer from partial deficiencies for unidentified growth substances present in the malt, a possibility which was not investigated.

Attention was called to certain differences between the effect of the vitamins in the agar medium and in the liquid medium. These differences were quantitative rather than qualitative and may indicate that the power of some of the fungi to synthesize a particular vitamin from elementary substances is conditioned by the oxygen supply. A conditioned deficiency of this type has been described for *Staphylococcus aureus* in its relation to uracil (Richardson, 1936). On the other hand, the difference

may not be as great as appeared. Growth on agar slants can be estimated but not measured accurately in terms of dry weight; a small amount of mycelium spread over the surface of an agar slant may give the impression of a greater dry weight than actually exists.

C. pluriannulata produced perithecia when furnished thiamine and pyridoxine; it grew quite well but formed no perithecia on an agar medium supplemented with pyridoxine. Hawker (1939) found that *Melanospora destruens* grew on a medium supplemented with biotin but formed no perithecia; perithecia were produced on a medium containing biotin and thiamine. These observations show a relation between vitamin supply and the production of sex organs by certain fungi. It is doubtful, however, that this relation is direct. We are inclined to regard failure to produce perithecia in the absence of thiamine, for example, as a symptom of a fundamental disturbance in the physiology of the organism. We anticipate that other vitamins may be found associated with the production of sex organs by other fungi, and that the vitamins which are found to be active will depend upon the deficiencies of the organism concerned.

We may assume on the basis of previous results (Robbins and Ma, 1942) that each fungus is able to synthesize from the constituents of the basal medium those vitamins for which it shows no deficiency, and some, but inadequate, amounts of those for which it evidences a partial deficiency. *Ceratostomella stenoceras* and *Endoconidiophora paradoxa*, for example, without doubt synthesize biotin and pyridoxine when grown in a thiamine medium. *Ophiostoma catenium* may be assumed to synthesize thiamine and biotin when grown in a medium containing pyridoxine.

It appears clear that in a mineral-dextrose medium containing asparagine the growth of the majority of these fungi is limited by the supply of thiamine, pyridoxine or biotin. However, the question as to what limits their growth when these three

vitamins are available is unanswered. Why, for example, is the growth of *Ceratostomella penicillata* so much slower in the vitamin medium (or the malt medium) than that of *Endoconidiophora paradoxa*? Our observations raise many problems which require a detailed investigation of individual organisms.

SUMMARY

Thirteen species of *Ceratostomella* and related fungi were grown in a mineral-dextrose medium containing asparagine, and in the same medium supplemented with thiamine, pyridoxine or biotin, singly and in combination, or with malt extract. Eleven of the species suffered from complete or par-

tial deficiencies for one or more of the three vitamins. Six had complete or nearly complete deficiencies for pyridoxine, four for thiamine, and four for biotin.

Ceratostomella obscura showed a complete deficiency for pyridoxine and biotin, and *C. microspora* for all three vitamins. Six of the fungi grew markedly better in a medium supplemented with malt than in media supplemented with the three vitamins.

OBSERVATIONS ON THE FLOWERING HABITS OF FOUR PASPALUM SPECIES ¹

Glenn W. Burton

A STUDY of the blooming process in plants often results in the discovery of features peculiar to individual species which may be utilized to facilitate the manipulation and hybridization of those species in a breeding program. Since May, 1936, when the grass breeding project at the Georgia Coastal Plain Experiment Station, Tifton, Georgia, was initiated, numerous observations on the anthesis of the improved grasses in the Southeast have been recorded. In this paper the blooming behavior of Dallis grass, *Paspalum dilatatum* Poir. Vasey grass, *Paspalum urvillei* Steud.; Bahia grass, *Paspalum notatum* Flügge; and *Paspalum malacophyllum* Trin. as related to certain climatological factors is presented.

Many publications dealing with the flowering habits of the cereals and more common northern grasses appear in the literature. In the absence of papers describing the flowering habits of the Paspalums, some of these publications have been reviewed and will be considered in the interpretation of the data presented in this paper.

OBSERVATIONS.—With the exception of a few potted plants used in dark-room studies, all of the follow-

¹ Received for publication August 29, 1942.

Cooperative investigation at Tifton, Georgia, of the Division of Forage Crops and Diseases, Bureau of Plant Industry, U. S. Department of Agriculture, the Georgia Coastal Plain Experiment Station, and the Georgia Experiment Station. The writer is indebted to Fred Bell, Jr., Agent, U. S. Dept. of Agriculture, Tifton, Georgia, for assistance in making many of the observations reported herein.

ing observations were made on well established field plantings of each of the species growing at Tifton, Georgia. Night observations were made by subjecting the panicles to light from a small flashlight at intervals only long enough to procure the necessary records. Representative panicles of the four *Paspalum* species considered here are shown in figure 1.

Heading period.—The cereals and many of the northern cultivated grasses head at a definite season of the year and complete their blooming process in a relatively short period of time (Evans, 1916; and Evans and Ely, 1941), usually from one to three weeks. The *Paspalum* species considered here, with the exception of the Paraguay strain of Bahia grass, begin to head in May and June and, except under very adverse environmental conditions, produce heads continuously until late October. The strain of *Paspalum notatum* from Paraguay has a major heading period of about four weeks followed by the formation of few if any panicles.

Table 1 indicates that the initial heading date in these Paspalums may vary a month or more from year to year depending upon certain climatological factors. Since all of these grasses head on both longer and shorter days and at higher and lower temperatures than those experienced in May and June, it is evident that photoperiod or temperature level are not directly responsible for the initiation of panicles in these grasses each spring.

Fig. 1. Left to right are representative panicles of *Paspalum malacophyllum*, *P. dilatatum*, *P. urvillei*, and *P. notatum*, $\times \frac{1}{2}$.

Evans (1939) working with timothy has shown that "for each degree of average daily temperature above the mean (during April, May and June), the average date of full bloom was advanced two days earlier than the medium, and for each degree below the mean, the date when the maximum number of plants were in full bloom was delayed two days. A somewhat similar relation between spring temperatures and heading date was observed in these Paspalum

lums in 1938 and 1939, but the severe winter injury in 1940 and the April-May drought of 1941 apparently obscured these spring temperature effects. These observations suggest that any climatological factor that noticeably delays spring growth such as winter injury, low spring temperatures, and spring drought will delay heading in these Paspalums.

Blooming process.—Under favorable conditions for blooming all of the Paspalums in this study fol-

low the same general blooming procedure. To facilitate the recording of observations this procedure has been divided into four empirical stages which are demonstrated with florets of *P. notatum* in figure 2. The first stage in this process consists of the

Fig. 2. Florets of *Paspalum notatum*, $\times 6$, demonstrating empirical stages in the blooming process of the Paspalums.—a. At stage 1 the glumes begin to open.—b. At stage 2 the filaments begin to elongate exerting the anthers.—c. At stage 3 the anthers are completely exerted.—d. At stage 4 the anthers dehisce shedding pollen.

opening of the fertile floret. The beginning of the exertion of the anthers marks stage 2. At stage 3 the anthers are completely exerted, and in stage 4 the anthers dehisce shedding pollen. Usually the glumes close soon after the pollen is shed.

Under less favorable conditions many variations from the normal blooming process have been observed. In a dry atmosphere the anthers usually dehisce very soon after the glumes open and before they are completely exerted. Frequently, under such circumstances, the glumes will close so quickly after opening that none or only small portions of the anthers and stigmas will be exerted. Flowers which have retained one or more of the anthers or stigmas within the glumes are frequently found in these grasses, particularly in *P. notatum*.

Order of blooming.—The order of blooming in these Paspalums has been observed many times. Usually less than half of the florets on any one raceme bloomed in any twenty-four-hour period, and frequently three to four days elapsed between the initiation and completion of anthesis in any one raceme. There was a marked tendency at all times for the florets in the terminal portion of the raceme to

bloom first, but frequently the florets at the very tip of the raceme did not bloom until the second or third day.

In *P. malacophyllum*, *P. dilatatum* and *P. urvillei* which have more than two racemes per panicle (fig. 1), anthesis began in several of the uppermost racemes. These three species also have paired spikelets crowded into four rows along the entire length of the raceme. Here the outer spikelet of the pair almost invariably bloomed one or more days earlier than the inner spikelet.

The average number of days required to complete anthesis in single panicles of these *Paspalum* species in June, 1941 (based on observations on 25 panicles of each grass), was 4.3 for common *P. notatum*, 4.6 for Paraguay *P. notatum*, 5.6 for *P. dilatatum*, 8.1 *P. malacophyllum* and 8.2 for *P. urvillei*.

On the basis of extensive studies with a number of northern cultivated grasses (*Phleum*, *Poa*, *Festuca* and *Lolium* species) Fruwirth (1916) concluded that blooming begins in the upper third of the inflorescence, at the end of a single branch in panicles and is completed in any one panicle in from four to eight days, depending upon the species. The similarity between these northern and southern grasses is apparent.

Time of blooming.—The hour at which each floret on twenty panicles of *P. notatum* bloomed was recorded from 4 A.M. to 8 P.M. for the period July 27 to August 1, 1936. To facilitate record taking anthers were removed from each flower as soon as its blooming was recorded. Weather records taken at hourly intervals for this period included air temperature, soil temperature at a depth of two inches, relative humidity and general weather conditions, whether clear, cloudy, or rainy. These data are presented graphically in figure 3.

From July 27 to July 30, a period of fair weather, 97.6 per cent of the 1190 flowers that bloomed, did so between 6:00 and 8:00 A.M. On August 1, a cloudy day with slow intermittent showers, the blooming was spread over a much longer period of time and only 31.2 per cent of the 144 flowers blooming on that day bloomed between 6:00 and 8:00 A.M. Although, as figure 3 indicates, a few florets bloomed on the afternoons and nights of the rainy days, most of the *P. notatum* flowers bloomed between 6:00 A.M. and 12:00 noon. Many more recent observations indicate that the above statements generally describe the blooming behavior of this species.

General observations made on plantings of *P. dilatatum*, *P. urvillei* and *P. malacophyllum* from July 27 to August 1, 1936, revealed that practically all of the florets of these grasses blooming in any twenty-four-hour period bloomed early in the morning. *Paspalum malacophyllum* was the only grass that failed to bloom on the rainy days of July 31 and August 1.

From June 15 to 24, 1939, the anthesis of the Paspalums considered here was carefully observed from 3:30 to 8:30 A.M. The hour when the majority of the florets started to bloom and the time in minutes

TABLE 2. The average hour, Eastern Standard Time, when anthesis began and the average time in minutes required to reach blooming stages 2, 3 and 4 (see figure 2) in several *Paspalum* species at Tifton, Georgia, during the ten-day period July 15-24, 1939.^a

Stage of anthesis (see figure 2)	Hour of initial blooming and minutes required to reach subsequent stages in:				
	<i>Paspalum malacophyllum</i>	<i>Paspalum dilatatum</i>	<i>Paspalum urvillei</i>	<i>Paspalum notatum</i>	<i>Paspalum notatum</i>
	A.M.	A.M.	A.M.	(common) A.M.	(Paraguay) A.M.
1	3:58 ^b	6:25	5:12	6:19	5:32
2	5.4	5.7	5.8	7.0	7.7
3	13.2	12.0	10.9	13.0	15.4
4	19.6	18.9	16.7	21.4	26.1

^a The records above apply to the period when the majority of the florets were blooming. Usually a number of florets bloom both before and after the period of intense blooming, particularly in *P. urvillei* and *P. malacophyllum*.

The sun arose about 5:30 A.M. Eastern Standard Time during the course of this study.

^b On two days following rains of the previous night *P. malacophyllum* did not bloom and on two other days it had finished blooming by 3:30 A.M., the time when the first observations were taken.

required to reach subsequent blooming stages were recorded for each grass for each day of the observation period. The ten-day average of these data is presented in table 2. During this ten-day observation period rather large day to day variations in the hour when blooming began and in the time required to reach different stages of blooming were observed.

The differences between the earliest and latest hour when blooming began exceeded one hour for *P. malacophyllum*, *P. urvillei* and *P. dilatatum* and amounted to twenty-six and fifty-three minutes for the common and Paraguay strains of *P. notatum*. Anthesis was observed to progress at a faster rate on warm mornings than on cool cloudy mornings.

Fig. 3. The hours at which the florets on twenty panicles of *Paspalum notatum* bloomed in the field at Tifton, Georgia, for the period July 27 to August 1, 1936, as related to certain features of the environment.

According to Beddows (1931), Fruwirth (1916), Jenkin (1924) and Wolfe (1925) many of the northern cultivated grasses bloom most abundantly in the early morning. Fruwirth (1916), working in Germany, observed that most of these species had a secondary, less intense blooming period in the afternoon, usually from 4:00 to 6:00 P.M. He reported that the blooming of a single floret usually lasted one to two hours and concluded that weather conditions exercised "a great influence" on the time of blooming. The *Paspalums* considered here bloomed in the early morning, did not have a secondary blooming period in the afternoon and completed anthesis in single florets within fifteen to thirty minutes. Weather conditions, as in the case of the northern grasses, influenced the time and rate of blooming.

ADDITIONAL OBSERVATIONS.—Potted plants of *P. dilatatum*, *P. urvillei*, and both strains of *P. notatum*, when placed in a photographic darkroom in the late afternoon, bloomed little if any on the following day unless exposed to light. When subjected to daylight before 8:30 A.M. on clear days (as late as noon on cloudy days) or to a 100 watt Mazda light in the darkroom, these panicles bloomed normally. In each instance air temperatures were not above 80 degrees Fahrenheit. Later in the day when air temperatures were above 80 degrees F. those florets exposed to light either failed to bloom or opened and closed so rapidly that the floral organs were never completely exerted.

In the field, light-proof paper bags placed on panicles of these *Paspalums* in the late afternoon delayed flowering on the following morning. If on the following day these bags were removed between sunrise and 8:30 A.M. on clear days or before noon on cloudy days, normal blooming usually followed. When these bags were removed later in the day at air temperatures above 80 degrees Fahrenheit, the panicles either failed to bloom or bloomed abnormally.

Some florets of *P. urvillei* usually bloomed in the darkroom or in light-proof bags. This response was expected, since many florets on unbagged panicles of this species frequently bloom before dawn.

Paspalum malacophyllum has invariably failed to bloom on rainy days or on days immediately following rainy days, whether in the field or in the greenhouse. The other four *Paspalums* have bloomed in the greenhouse during heavy rains and have been observed blooming between showers in the field.

On foggy or misty mornings the florets of these grasses have remained in stage 3 of the blooming process (the anthers exerted but not dehiscent) much longer than usual. In order to determine experimentally the effect of mist upon anthesis, panicles of *P. notatum* and *P. dilatatum* were placed in a large cloth-covered box in which an atomizer created a continuous fine mist of water. On clear days when untreated panicles had bloomed by 8:00 A.M., florets on panicles enclosed in this artificial mist box started to bloom but remained in stage 3 until they

were removed from the mist at noon. These observations suggest that stage 4 in the blooming process (the dehiscence of the anthers) depends upon desiccation and may be greatly delayed in a mist-laden atmosphere.

Since these *Paspalums* bloom and shed pollen in the early morning, it is often difficult to collect pollen for hybridization purposes without getting it wet with the dew accumulated on the plants. When panicles of these grasses were cut, placed in water and brought into the laboratory either during or a few minutes before the blooming process, reasonably normal anthesis followed and a fair to good yield of dry pollen was easily obtained. These panicles usually bloomed little if any on subsequent days. *P. urvillei* responded least favorably to this treatment. When cut panicles were brought into the laboratory in the late afternoon, *P. malacophyllum* was the only one of these grasses that bloomed well and produced an abundance of pollen on the following morning. Panicles of *P. malacophyllum*, cut on the afternoons of rainy days and brought into the laboratory, responded as uncut heads in the field or greenhouse and failed to bloom during the next day.

Fruwirth (1916), studying the northern cultivated grasses, noted that the rate of blooming increases with temperature and stated "if there is not sufficient warmth available, blooming does not take place at all." He observed that the lack of light will delay blooming somewhat. He reported that although "high humidity" does delay the opening of the anthers it does not hinder blooming.

SUMMARY

During the four years 1938 to 1941, *Paspalum malacophyllum*, *P. dilatatum*, *P. urvillei* and common *P. notatum* produced panicles continuously from May or June until October. The Paraguay strain of *P. notatum* usually formed many panicles for about one month and relatively few thereafter. Generally *P. malacophyllum* bloomed an hour or more before sunrise, *P. urvillei* began to bloom before dawn but frequently had not finished by sunrise, Paraguay *P. notatum* bloomed about sunrise and *P. dilatatum* and common *P. notatum* bloomed from thirty minutes to an hour later.

Usually less than half of the florets on any one raceme bloomed during any twenty-four-hour period. Flowers in the terminal portion of the raceme and in the uppermost racemes in the panicle tended to bloom first. The outer spikelet in those species having paired spikelets (all but *P. notatum*) almost invariably bloomed first. Usually from fifteen to thirty minutes were required to complete the blooming process in any one floret.

Several controlled experiments indicated that anthesis in *P. urvillei*, *P. dilatatum* and *P. notatum* may be delayed several hours by excluding entire plants or just panicles from light. Within a rather narrow temperature range the rate of anthesis increased with temperature. These *Paspalums* either failed to flower or bloomed in a very abnormal man-

ner when air temperatures exceeded 80 degrees Fahrenheit. Mist, either natural or artificial, delayed dehiscence of the anthers and indicated that dehiscence is dependent upon desiccation.

P. malacophyllum was the only one of these grasses that failed to bloom on rainy days or on days immediately following rainy days, whether in the field or in the greenhouse.

SPORELINGS AND VEGETATIVE REPRODUCTIVE STRUCTURES IN *MASTIGOLEJEUNEA AURICULATA*¹

Margaret Fulford

BOTH SPORELINGS and vegetative reproductive bodies from leaf cells were observed recently in the tropical and subtropical hepatic, *Mastigolejeunea auriculata*. Neither of these structures has been previously reported for the species, so that not only are the patterns of development in themselves of interest, but they afford the not too frequent opportunity of a comparison of development of young plants of a species from two points of origin, namely, the spore and the leaf cell. In addition to this, the vegetative reproductive structures develop from the apparently mature leaf cells which dedifferentiate before they divide to initiate the development of the new plant.

Evans (1902) has given a detailed description and figures of the mature plant so that only a very brief outline need be repeated here. The plants usually grow on banks in green to brownish depressed mats. The stems are often 2 cm. in length and the leafy shoots may be 2.5 mm. wide. The branches are of the *Lejeunea* type, are widely spreading and may be microphyllous or flagelliform. The leaves are ovate-oblong, up to 1 mm. in length and have a characteristic water sac (fig. 19). The underleaves are broadly orbicular, and may be up to 0.55 mm. long. The leaf cells of the apical portion average $24 \mu \times 16 \mu$. The walls are thin but have conspicuous trigones and intermediate thickenings.

THE SPORELING.—Sporelings were found in abundance in material collected at Troy, Jamaica, by Dr. Evans. At the time that the spores are shed they are

typical for spores formed in tetrads; that is to say, each has three flat, triangular surfaces and a bulging, rounded surface. The wall is densely echinate and hyaline (fig. 1), and the spore is green because of its chlorophyll content. With the increase in available moisture the spore becomes spherical. At about this time four cells can usually be distinguished, separated by walls more or less at right angles to one another within the original spore wall (fig. 2). Further divisions occur in one direction faster than in the others, and very soon the young sporeling is elongate ovoid and contains a fairly large number of cells (fig. 3 and 4). The echinate exospore is plainly visible and for a time forms an even covering over the whole cell mass. However, as these cells reach maturity they tend to become rounded on the free surface, so that in the leafy sporeling this basal portion which retains the echinate spore wall is irregular in outline and suggests a compact bunch of grapes (fig. 5 and 6). The multicellular body is usually about 60μ long when further cell divisions and growth cease, and the apical cell with three cutting faces is formed at one end. This in turn initiates the growth of the leafy shoot.

The leafy shoot first formed has only two rows of leaves. These are plane and ovate and represent the primary leaves, similar in character to those found in the sporelings of *Lopholejeunea*, *Stictolejeunea* and certain other of the leafy liverworts. As in the genera just mentioned there are no underleaves associated with the primary leaves. The formation of this type of leaf continues for some time, and it is assumed that under favorable conditions a more advanced stage of development is soon attained which will result in the formation of typical juvenile leaves and underleaves. This pattern of development of the sporeling conforms to the *Frullania* type (Fulford, 1942).

¹ Received for publication August 31, 1942.

This work was done during a study of tropical American Hepaticae made possible through a John Simon Guggenheim Memorial Fellowship 1941-1942.

The writer wishes to thank Dr. A. W. Evans of Yale University for his kind assistance, and the members of the Botany Department of Yale University and the New York Botanical Garden for facilities for study during the course of the work.

VEGETATIVE REPRODUCTION.—This phenomenon was observed in only two collections,² one from Costa Rica and the other from British Guiana, although the species is widespread in tropical and subtropical America from southern Florida and Mississippi through the West Indies, Mexico, and Central America to northern South America and is collected very frequently.

The vegetative reproductive structures are produced only on the leaves. These appear to be "normal" in every way and in no respect different from those of the rest of the plant or of other plants. They give no indication of being old, nor are they "eroded" or weathered as is the situation in *Bryopteris* (Fulford, 1941). The new plants usually develop in large numbers on the dorsal surface of a leaf (fig. 19), with a few on the ventral surface.

² The material from Costa Rica was collected by Professor Alfaro, at 'El General,' 720m., and is in the herbarium of Field Museum; that from British Guiana was collected by Professor P. W. Richards and is in the herbarium of Yale University.

Whether this is the result of an inherent polarity or of some external stimulus has not yet been demonstrated.

There is no evidence that the cells giving rise to new plants are not mature and like the other leaf cells. They have relatively thick walls with conspicuous trigones, but the cytoplasm and nuclei are difficult to demonstrate in dried material. The first step in the development of the new plant is apparently the dedifferentiation of the mature cell, and in this process the cytoplasm becomes granular and very conspicuous and the nucleus greatly enlarged.

Very soon a cell of this sort bulges on the dorsal surface of the leaf (fig. 7). The enlargement is followed by a transverse division at right angles to the long axis of the cell, so that two bulging cells are formed (fig. 8). Each of the two cells gives rise to a leaf of the primary type. Each cell divides into two cells through the formation of a wall at right angles to the first wall and also to the surface of the leaf (fig. 9 and 10). The two-celled stage is followed by additional divisions, until the characteristic pri-

mary leaf is formed (see fig. 9–17). During the development of this first pair of primary leaves the newly formed apical cell with three cutting faces, which will give rise to the rest of the shoot, is also active. It becomes evident at about the time that the first pair of leaves has reached the two-celled stage, but the details of its origin are so difficult to observe that the method of formation has not yet been determined.

The details of development of the ventral segments are not easily observed. It appears that they are cut off as soon as the apical cell becomes active, but that they form only stem tissue. It would seem that the first ventral segment cut off (*x*, fig. 11) divides to form two cortical cells (*x*, fig. 13), but the subsequent ventral segments give rise to only one cortical row and internal tissue, for the fully developed stem bearing primary leaves—always without underleaves—has only one row of cortical cells which are ventral in position (fig. 18). The cells of this row give rise to occasional rhizoids. The same situation is no doubt present in the leafy sporeling so long as primary leaves are formed, since here, also, no underleaves are present.

The leaves formed from the later lateral segments are similar to, but somewhat larger than, the first pair which were formed from the bulging leaf cells. They are plane and broadly ovate and are also of the primary type, with no indication of a water sac (fig. 17 and 18). Stems with as many as ten pairs of these leaves are not infrequent.

As in the case of the sporelings, no plants having juvenile leaves with the characteristic water sacs were found.

The new plants readily become separated from the parent leaf, and leave an empty space in the original cell network. Some traces of the first cross wall are often left behind.

There were many instances in which death of a leaf cell had occurred just after the change in the cell content was evident, or after the cell had enlarged or after a cross wall had formed, all of them recognized by a brown discoloration of the cell content, walls and trigones.

We have here another example of mature, differentiated cells which have retained their ability to divide. In addition to this, they are totipotent. The reason for the infrequency of expression of this ability and the external or internal stimuli which initiate it are not known. The development of the young leafy plant proceeds directly from the leaf cell without an intervening protonemal stage characteristic in some forms. In fact, the development is so direct that the two cells formed by the initial division of the leaf cell give rise to the first pair of leaves. Other examples of this nature in which the leafy shoot proceeds directly from the leaf cell have already been cited for this family by Evans (1906) and others.

The developmental pattern of the sporeling and the vegetative reproductive body are similar except for the fact that the initial stage of the sporeling, the ovoid cell mass, is absent in the latter. The general habit, the form and structure of the primary leaves, the absence of underleaves, and the stem are the same.

This same pattern of vegetative reproduction is present also in the South American *M. plicatiflora* and is no doubt characteristic of the genus.

SUMMARY

The pattern of development of the spore of *M. auriculata* is of the *Frullania* type; that is, an ovoid mass of cells is formed within the much stretched exospore.

The apical cell with three cutting faces develops at one end of this cell mass, and the leafy stem is formed through its activities.

The vegetative reproductive bodies are in the nature of leafy stems developed from individual cells of the mature leaf.

The mature leaf cells not only have the capacity to dedifferentiate and to divide; they are also totipotent.

No protonemal stage is formed, since the new leafy stem develops directly from the leaf cell; the two cells formed from the initial division of this leaf cell, through subsequent divisions, form the first pair of leaves.

The early leaves of both the sporeling and the vegetative reproductive structures are of the primary type, without water sacs, and often ten or more pairs are formed. Underleaves are not associated with these leaves.

During the stage when leaves of the primary type are formed the ventral segments give rise to one row of cortical cells and a portion of the medulla of the stem.

In this genus the pattern of development of a plant from a leaf cell follows that of the sporeling, except that it does not have the protonemal stage.

THE THREE-DIMENSIONAL SHAPES OF UNDIFFERENTIATED CELLS IN THE PETIOLE OF ANGIOPTERIS EVECTA¹

Noe Higinbotham

ONE of the most striking features of higher plants and animals is the physiological and structural diversity of their cellular tissues. Since the peculiarities of structure in given tissues are particularly revealed in the shapes of their cells, an analysis of the three-dimensional shapes of these cells should greatly increase the understanding of organization and differentiation in plants and animals alike.

In general, several types of investigation have a bearing on the problem of cell shapes. First, Lewis (1923, 1925, 1933a, and 1933b), Marvin (1939a), and Hulbary (1940) have concerned themselves with analyses of the actual three-dimensional shapes of mature cells in which, presumably, the forces determining shape have attained an equilibrium. Second, work with physical systems by Marvin (1939b) and Matzke (1939 and 1940a) has shown that pressure in lead shot and surface tension in soap bubbles produce shapes comparable to those of actual cells. In all cases the average number of contacts per cell or polyhedron in a central position approximated fourteen although the number of polyhedra having exactly fourteen facets was sometimes less than those having thirteen or fifteen. Thus the tetrakaidecahedron, or polyhedron with fourteen facets, is not necessarily achieved, though it might be said to represent the average. Third, studies of development such as those of Sinnott and Bloch (1939, 1941) indicate that plant cells undergo no drastic rearrangement in growth and, therefore, that the plane of cell division is often a primary factor in cell shape.

LITERATURE REVIEW.—A comprehensive review of the literature on cell shape has been given in a recent paper by Marvin (1939a) who has traced the interest in the three-dimensional shapes of cells from the time of Hooke and Grew in the seventeenth century through to the recent work of Lewis, Matzke, and others. Even more recently Matzke (1940b) has written a concise digest of the problem as it stands now. For this reason only the more pertinent and recent papers will be mentioned here.

The first actual investigation of the three-dimensional shapes of massed cells was made by Lewis (1923). By means of serial sections of elder pith he found that for a hundred cells the average number of contacts was 13.97 per cell. In a discussion of the problem from a biological standpoint Lewis concluded that, despite various modifying factors, elder pith cells approximated the orthic tetrakaidecahedron as described by Lord Kelvin in 1887. This figure is a polyhedron having fourteen facets, six squares and eight hexagons, and has several features which might be expected in cell masses. First, the figure has dihedral and trihedral angles but no tetra-

hedral angles which are less stable; second, it is very economical in its surface-volume relationships; and third, such figures will stack to fill space without interstices.

Lewis found no cell in the elder pith which conformed perfectly to the orthic tetrakaidecahedron nor did he find any in his later studies of human fat and tadpole precartilaginous cells. His observations showed that there were more pentagonal facets than either the square or the hexagonal facets expected if cells were orthic tetrakaidecahedra. He pointed out, however, that cell division and differences in cell size may modify the shape of a cell and, further, he showed how some of the cells found might be derived from the orthic tetrakaidecahedron. Thus his conclusion was that fundamentally cells have the three-dimensional form of the orthic tetrakaidecahedron.

Marvin (1939a) has recently reported a thorough investigation of a hundred pith cells of *Eupatorium*. Using a new technique (Marvin and Matzke, 1939) in which the cells were impregnated with wax and the resulting wax models separated, he was able to study each contact surface of every cell under a dissecting microscope. The average number of facets for the 100 cells was 13.36.

One of the most important features of the cell studies is the investigation of cell volumes. Started by Lewis, this line of investigation was greatly extended by Marvin (1939a) who made accurate, greatly enlarged, paper models of each of the 100 pith cells that he studied. The results of this work showed that smaller cells had fewer than fourteen contacts and larger cells more than fourteen contacts; that smaller facets had fewer edges than larger ones; and that the surface to volume relationships of cells closely approached the economy of surface found in the orthic tetrakaidecahedron or rhombic dodecahedron of equal volume. This last is a very important discovery for it shows that a high degree of economy of surface may be present in cells of undifferentiated tissues despite differences in volume and irregularities in shape of the cells.

Recent experimental work which seems to be closely related to cell shape has been reported by Marvin (1939b). Lead spheres of uniform diameter were subjected to compressive forces ranging up to 35,000 lbs. per sq. in., at which pressure all interstices were eliminated and an average of 14.17 contacts was established in the central shot. A lesser pressure (22,500 lbs.), in which some interstices remained, gave an average of 13.62 for the central shot.

Matzke (1939) studied compressed lead shot of different sizes, one having twice the diameter of the other. Various mixtures of the two showed that the smaller shot always had an average of less than fourteen facets. The averages of the central shot in

¹The author is deeply grateful to Professor Edwin B. Matzke for innumerable aids during the course of this research at Columbia University and its subsequent preparation for publication.

TABLE 1. Distribution of the 100 cells according to number of contacts per cell.

Number of contacts	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22
Number of cells	2	2	7	11	15	19	14	7	8	7	4	1	1	0	2

different experiments, small and large considered together, varied from 13.0 to 13.8 facets.

Further work by Matzke (1940a) on soap bubbles of uniform volume showed that a surface tension system also gave an average number (13.69) of contacts per polyhedron which approximated fourteen. Other striking results found in the study of soap bubbles were the large number of polyhedra with the same combinations of facets, the large number of pentagonal dodecahedra, and the greater proportion of pentagonal facets in general.

MATERIALS AND METHODS.—Since spermatophytes have been used in all previous botanical studies of cell shape, a pteridophyte, *Angiopteris evecta*,² was chosen in the present case in order to compare results in distant plant groups. The basal portion of an *Angiopteris* petiole, about 1½ inches in diameter, was fixed in 95 per cent ethyl alcohol. A cross section at this point showed a large number of vascular bundles loosely arranged in five to six rings within the ground tissue, or parenchyma. The parenchyma made up the bulk of the petiole and provided the cells reported on here.

Portions of the petiole were first cut into transverse sections about four to six cells in thickness. These sections were stained with safranin in 95 per cent alcohol, then gradually transferred to xylol, after which small rectangular blocks, approximately 0.5 mm. across, were cut longitudinally from the ground tissue between the bundles. The small blocks, containing from ten to thirty whole and unimpaired parenchymatous cells, were then placed in a mineral oil (Nujol). It was found possible to orient a block in any position in the mineral oil while studying the cells of the block under a binocular dissecting microscope. Thus any given facet of a cell could be seen in plane view when using a magnification of 100 diameters or more. In this way the number of contacts of each of a hundred cells was ascertained, and the number of edges on each contact was tabulated. Unless otherwise specified only contact facets have been considered as true cell facets. These hundred cells were not taken at random, but instead all the whole cells in a single block were studied and numbered in sequence before proceeding to another block. Six blocks were sufficient for the hundred cells. A schematic drawing showing the position of the cells was made of each block, so that it was possible to refer back to any given cell.

Shrinkage due to alcohol fixation may have affected slightly the size of intercellular spaces observed, but there is no evidence to indicate any significant alteration in the types of spaces, since these may be seen in the living tissue.

²The author wishes to acknowledge his appreciation to the New York Botanical Garden for material of *Angiopteris evecta*.

OBSERVATIONS.—In general the undifferentiated cells in the *Angiopteris* petiole are nearly isodiametric and tend to be irregularly arranged, unlike so many stem pith cells which lie in long continuous rows. Often, however, short, more or less irregular rows can be discerned. There is an indication of this in the photomicrograph of block 5 (fig. 1). The cells here vary considerably in size, and the tissue has some intercellular spaces. The two cells encircled in the photomicrograph (fig. 1) are also shown in figure 2.

Fig. 1. Photomicrograph of a block of cells from the ground tissue of *Angiopteris* petiole. $\times 34$. The arrow indicates the approximate direction of the long axis.

A study of one hundred cells gave an average of 13.55 contacts. In *Angiopteris*, as can be seen in table 1, cells with thirteen contacts were the most frequent, being nineteen in number, but nearly as many, fifteen, had twelve contacts and fourteen of the hundred cells had exactly fourteen contacts. The range was from eight to twenty-two contacts but eighty-eight of the cells fell in the range between ten and seventeen. There was one break in the range of eight to twenty-two contacts, since no cells with twenty-one facets were found.

Volumes of cells were not measured, but the camera lucida drawings indicate (as found by Marvin, 1939a) that the cells with a lesser number of facets (fig. 3, 4, 5, 7) were smaller than the many-faceted cells (fig. 2, 8). On the whole, cells with twelve to fifteen facets were medium sized (fig. 6, 9, 10, 11).

In *Angiopteris* several of the cells studied were separated by intercellular spaces which quite possibly reduced the average of contact-facets per cell. One of these intercellular spaces is shown as a stippled area in figure 16, in which two cells barely miss contacting one another. Each of these intercellular

Fig. 2-16. Camera lucida drawings of some of the *Angiopteris* cells studied. $\times 150$. The number of contacts of each cell is followed by a specification of their shapes: T-triangular; Q-quadrangular; P-pentagonal; H-hexagonal; Hpt-heptagonal; O-octagonal.—Fig. 2. Cells 65 and 66. spaces was surrounded by six cells and in one view showed two cells close together but not in contact (fig. 16), while the other view showed four cells surrounding a quadrilateral space (as fig. 15 with four cells shown at the sides while fifth and sixth cells—not shown—occupied positions above and below the plane of the drawing). In such cases it does not seem unlikely that the intercellular space has arisen from the separation of cells, and thus in a sense it represents a lost contact for each of the two proximal cells. For this reason, and for the sake of convenience, those regions at which one cell

barely failed to contact another cell through the intervention of an intercellular space have been termed "lost contacts."

In figure 11 the stippled areas represent two "lost contacts" on one cell. Other cells with lost contact areas are shown in figures 8 and 12. In general the larger air spaces causing lost contacts were associated with cells adjacent to one another but differing markedly in size.

In addition to the larger air spaces numerous smaller interstices were observed along the edges. Often they completely encircled a facet so that the

Fig. 15. An intercellular space at which 4 facets of cell 96 meet.—Fig. 16. A "lost contact" between cells 28 and 27. Compare this figure with figure 14.

contact appeared circular rather than polygonal (see figure 13 for face view, figure 14 for side view; the air space is indicated by stippling). It was possible to find all the intergradations in size of air spaces from minute "edge spaces" to the comparatively large ones which separated two or more cells. The "edge spaces" however, are not "lost contacts," since they do not affect the total number of contacts in a cell. In all, twenty-six "lost contacts" due to the presence of intercellular spaces were found in the hundred cells. If these twenty-six "lost contacts" were added to the total, the average number of facets would be increased to 13.81, which is considerably closer to fourteen.

Nearly all the data of this study have been included in table 2, which gives the number and kind of facets for each of the hundred cells. The cells are grouped according to number of facets and are on the same line if the combinations of facets are alike. The tabulation of the kind of facets found in the hundred cells shows that pentagons were most common by far. Of all the facets, 44 per cent were pentagons, 26 per cent were quadrangles, and 21 per cent were hexagons. An appreciable number of heptagons were found—7 per cent in all. These four kinds of facets, quadrangles, pentagons, hexagons, and heptagons, composed 98 per cent of all the facets. The remaining small number of the facets were triangles, octagons, and one nonagon.

At the bottom of table 2 may be seen the average per cell of each kind of facet, and thus the actual ratios of the kinds of facets. On the basis of approximate ratios a hypothetical average cell of *Angiopteris* would have four quadrangles, six pentagons, three hexagons, and one heptagon. It is obvious that this combination of facets would not fit together at all, since it gives an odd total number of sides, whereas in a polyhedron, such as a cell, each edge is shared by two facets always giving an even total number of sides.³ Marvin (1939a) found that *Eupatorium* pith gave a hypothetical average cell with four quadrangles, five pentagons, four hexagons, and one heptagon. This combination of facets is perfectly feasible mathematically, and three such cells were found in *Angiopteris* (table 2; see fig. 11).

The proportion of pentagonal facets found in *Angiopteris* was higher than that in other tissues reported heretofore—although in every case pentagons have been found to be the most common type. It is very interesting to note that Matzke (1940a, 1940b) observed that soap bubbles *en masse* actually showed more pentagonal facets than all other kinds of facets put together.

Reference to table 2 shows further that all the cells exhibit pentagonal and quadrangular facets, whereas hexagonal and other types of facets may be absent in certain cells. Three cells (table 2; see also fig. 3, 7) have only quadrangular and pentagonal facets. Needless to say such a predominance of quadrangles and pentagons (to the degree seen here) is

correlated with and tends to lower the average number of facets per cell in the type of system under consideration.

As expected, trihedral angles (2,294) were much more numerous than tetrahedral angles (8). With greater magnification, seven of the eight "tetrahedral angles" were seen in reality to be minute intercellular spaces at which four facets met (as in fig. 15), and only one of the "tetrahedral angles" actually approached geometric perfection. Nevertheless, since even these near-tetrahedral angles were so rare, 1 in 287, in undifferentiated tissue it seems obvious that the forces determining cell form in *Angiopteris* tend to avoid them. The appearance of small intercellular spaces at such angles is a mechanism whereby a more stable condition results (Lewis, 1933a).

Among the hundred cells studied certain combinations of facets were found to occur in two or more cells (see tables 2 and 3). Thus both of the two eight-faceted cells had the same combination, each having four quadrangular and four pentagonal facets. One of these cells is shown in figure 3. Of the seven ten-faceted cells found, four had four quadrangular, four pentagonal, and two hexagonal facets (see fig. 4). As may be seen in table 3, many other cases were found in which cells showed duplication in number and kinds of facets. It should be remembered, however, that this does not mean that the cells were exact duplicates of one another, inasmuch as they may vary in their different dimensions.

The average occurrence of any given facet combination (table 2) was 1.4 for the hundred cells.

TABLE 3. Combinations (of facets) occurring more than once in 100 cells.

³ For a more detailed discussion of the mathematics and geometry of cell shapes see Lewis, 1933a, 1933b.

This does not necessarily indicate a pattern of cells in mass which was repeated 1.4 times in the group of one hundred cells. There was a more frequent occurrence of certain combinations, and thus of cell patterns or arrangements (see table 3), than of other combinations. Presumably those arrangements of cells which tended to comply more exactly with the laws of surface tension and pressure occurred more often than others. For example, those cells with trihedral angles were much more frequent than those with tetrahedral angles.

The figures in table 3 show that there were more cases of similar combinations in the thirteen-faceted cells, which were most numerous, than in any other. However, there were no more than three cells of any given combination, so that no single cell-form type is predominant. Among the fourteen-faceted cells, four cells had the following combination of facets: three quadrangles, seven pentagons, three hexagons, and one heptagon (see fig. 9). Again no single combination is outstanding. The cells illustrated in figures 2, 10, and 11 are additional examples of combinations which occurred twice or more.

Marvin (1939a) also noted in *Eupatorium* pith that many cells were alike in having the same number and kinds of facets. A comparison of the cell data presented here with Marvin's results shows that in many instances the same combination of facets was found in the cells of both tissues. In the hundred cells of *Eupatorium* pith each of sixty-three was similar to one or more other cells, while in the present study of *Angiopteris* each of fifty-three of the hundred cells was found to be similar to at least one other cell. Some of the combinations which occurred only once in Marvin's study matched some of those occurring only once in the present report, so that, if the data of the two studies are lumped together, it is seen that a total of 127 cells had combinations of facets similar to one or more other cells. It is interesting to note that with four exceptions these 127 cells had trihedral angles only, and all their facets were four to seven-sided, while among the remaining seventy-three cells (of the 200 total) seventeen had tetrahedral angles, and twenty-five had one or more of the very infrequent triangular, octagonal, or nonagonal facets. Thus only thirty-one cells, "typical" in having trihedral angles and

four to seven-edged facets only, had unduplicated combinations. Of these thirty-one cells one had twelve facets, one had thirteen facets, two had fourteen facets, and most of the remaining twenty-eight had fifteen or more facets each. Studies of larger numbers of cells would probably reveal duplications of combinations found in these thirty-one cells.

In view of total numbers in the two hundred cells, tetrahedral angles (one tetrahedral to 204 trihedral angles) and facets with a number of edges beyond the range of four to seven (one in seventy-six) were very infrequent, so that cells having these structures might be considered as exceptions to the usual tendencies. If these cells are omitted as atypical, then 79 per cent of the cells studied belong to the group in which certain combinations occurred twice or more.

DISCUSSION.—From the standpoint of cell shapes, comparison of the undifferentiated cells of a fern (*Angiopteris* leaf) with undifferentiated cells from widely separated sources as reported by other authors (table 4) has revealed no fundamental differences. Although nearly isodiametric cells seem essentially alike wherever they occur, no single ideal figure has been found to predominate in actual tissues. Reference to table 4 shows in every case a wide range in number of contacts per cell despite the fact that most cells, 81 per cent of the 450 cells reported, have from eleven to sixteen facets each. The average cell of the 450 total has 13.84 contacts and thus approaches a fourteen-faceted polyhedron more nearly than any other entire geometric figure. Despite this average it should be noted that there were as many cells with thirteen facets as with fourteen facets.

The loss of contacts due to the formation of intercellular spaces of the schizogenous type is to be expected as a common occurrence in plant tissues. However, Lewis found numerous edge spaces in elder pith (1923) which did not affect the average number of contacts. *Angiopteris* petiole tissue shows that relatively small intercellular spaces may lower the average number of contacts. In general the "lost contacts" (see fig. 8, 11, 12) are smaller than the actual contacts between two cells. This indicates that during development there is either a lesser wall growth in the region of an air space or a tendency

for cells contacting one another with a small area to become separated.

The average number of contacts reported here for *Angiopteris* petiole, 13.55 for 100 cells, closely approaches the average 13.62 for lead shot when the shot was not compressed quite enough to eliminate all the interstices (Marvin, 1939b). Greater pressure on the lead shot eliminated all interstices and increased the average of contacts to 14.17. A similar increase in the average of contacts might be expected in *Angiopteris* cells if the air spaces could be eliminated.

Sinnott and Bloch (1941) have shown how the position of the new wall in cell division may affect cell shape. They found in certain grass roots that the position of the intercellular spaces was predetermined by the meeting of new cell walls to form four-rayed intersections. The air spaces always originated at the intersection. They further concluded that a pattern of cell division giving four-rayed intersections, as in certain grass roots, results in cells with ten facets each, and, if the walls are alternate in position avoiding four-rayed intersections, then an average of fourteen facets is to be expected.

In analyzing the shapes found in parenchymatous cells it is instructive to compare these shapes with those to be expected if a surface tension or interfacial film system is predominant. Surface films operating in cells would tend to give minimal surface area relative to volume, trihedral rather than tetrahedral angles, and a high proportion of pentagonal facets (see Matzke, 1940a). Marvin (1939a) has shown that, despite irregularities, cells do have an economy of surface area to volume relationship which compares favorably with both the rhombic dodecahedron and the orthic tetrakaidecahedron. All the cell shape studies (of compact undifferentiated tissue) have indicated a predominance of trihedral over tetrahedral angles. Matzke's study of soap bubbles (1940a) indicates that surface films may give many more pentagonal facets than any other kind. Pentagons are also much more frequent in cells than either quadrangular or hexagonal facets according to the present and previous reports. Thus ordinary parenchyma cells conform quite closely to the shapes expected of surface films.

The problem as to how, in special tissues, four-rayed intersections arise is not readily explained on the basis of surface films, however. Thus other forces such as turgor pressure and polarity—undoubtedly active in the process of differentiation—must be taken into account in proportion to their effect on cell shapes.

SUMMARY

The shapes of one hundred undifferentiated cells from the petiole base of *Angiopteris evecta* were studied by counting the number of contacts, or facets, per cell, and counting the number of sides of each contact. Instead of picking cells at random all the whole cells in six small rectangular blocks were studied.

The average number of contacts per cell was 13.55. In twenty-six cases cells barely missed contact through the intervention of intercellular spaces. Thus, in the absence of these intercellular spaces the average of 13.81 contacts per cell would be expected.

About 98 per cent of the facets of the cells studied were quadrangular (26 per cent), pentagonal (44 per cent), hexagonal (21 per cent), or heptagonal (7 per cent), while the range of facets was from triangular to nonagonal.

Nearly all of the 2,302 polyhedral angles were trihedral, only eight being classified as tetrahedral.

A number of cases were found in which more than one cell had the same number of each kind of facet. Thus four ten-faceted cells were found, each having four quadrangular, four pentagonal, and two hexagonal facets. In all, twenty-two combinations were found which occurred more than once in the hundred cells.

These observations and other data are discussed in relation to the theory that surface film forces predominate in determining cell shapes. Cell shapes do conform remarkably well with surface film expectations but do not achieve an ideal figure. Many factors other than surface film forces must be taken into account.

POLAR AND APOLAR TRANSPORT OF AUXIN IN WOODY STEMS¹

Jacob Oserkowsky

THE POLAR, basipetal transport of auxin in coleoptiles and young succulent stems of annual plants has been the subject of numerous investigations, but little study has been reported of auxins in stems of woody perennial plants. Such stems pass annually through active and inactive growth periods. Zimmermann (1936), Avery et al. (1937), Mirov (1941), Czaja (1934), van der Weij (1933) and Söding (1938) have shown the presence of auxins in woody stems. Van der Weij (1933) demonstrated polar movement of auxin in stems of *Elaeagnus angustifolia* Linn, and Michener (quoted by Went and Thimann, 1937) showed the same in *Salix*. The stems appear to have been used during the active period. Nothing seems to be known concerning auxin transport during the inactive or, as it is commonly termed, dormant season. Since changes occur during the dormant season which are important for subsequent growth, it seems desirable to learn something about the transport of auxin in dormant stems of plants which have a strong rest period. The purpose of this paper is to report studies on transport of auxin in pear and apple twigs during that part of dormancy which is termed the rest period, when the plants do not grow under otherwise favorable conditions of temperature, moisture and light. For purposes of comparison, certain experiments were carried out with newly-grown, non-resting tissues.

MATERIAL AND METHODS USED.—The resting twig sections used were obtained from one-year-old apple and pear trees kept in a warm greenhouse. The young, green sections were obtained from a group of trees similar in size and age to the resting trees, which, as a result of treatments with yeast extracts, opened several buds (Bennett and Skoog, 1938) and developed short shoots. The twigs were a few weeks old when used. The sections were 0.5 to 2 cm. long. The diameter of those from resting twigs was 3 to 4 mm., those from newly-grown twigs being somewhat smaller.

After cutting, the sections were floated on water for thirty to ninety minutes in order to wash the wound surfaces and to saturate the tissues with water. They were then dried with filter paper and sandwiched between two 1.5 per cent or 2.0 per cent agar blocks ($2 \times 2.7 \times 3.3$ mm.) either in the per-

pendicular or horizontal position, mostly the latter. The concentration of indoleacetic acid applied to the sections varied between 10 and 0.066 mgs. per liter of agar gel, and the amount applied per section varied between 0.300 and 0.002 micrograms (γ). The sandwiched sections were placed on glass slides inside a glass dish lined with moist paper. The tests were carried out at 25°C. except when otherwise stated. The sections were in contact with the agar blocks for periods varying from two to twenty-eight hours. The agar was then removed from the sections and tested for auxin content by the standard *Avena* test. In several instances the concentration of auxin in these blocks was too high to be measured directly, in which case a number of such agar blocks were placed in a test tube, a known amount of distilled water was added and allowed to stand in the dark at 0 to 2°C. overnight. The agar blocks were then placed on *Avena* coleoptiles, and their auxin content was determined after correction for the dilution factor. In a few cases, instead of soaking, the agar blocks were shaken in water at room temperature for several hours prior to placing them on the coleoptiles. In still other instances, the agar blocks were diluted with molten agar. When such dilutions were carried out, a set of agar blocks containing a known amount of indoleacetic acid, but previously not in contact with twig sections, was treated in the same manner and used as a check to correct for any loss of activity during the dilution process and during storage. All auxin data were based on eight to twenty-four *Avena* plants.

Agar blocks containing from three to five different concentrations of indoleacetic acid were tested with each set of samples. From the data thus obtained a curve of *Avena*-curvature vs. indoleacetic acid-concentration was constructed, from which the auxin content of the samples was determined by extrapolation or interpolation. This was done in order to correct for the daily variability in the sensitivity of *Avena* coleoptiles to indoleacetic acid, as well as for the deviation from proportionality of coleoptile curvature in relation to the concentration of this auxin. Some of the earlier data, however, were based on a single concentration of indoleacetic acid and strict proportionality was assumed between curvature and auxin concentration. Although such data are not accurate, they are valid for relative comparisons of treatments.

The extraction from twigs of both naturally occurring auxin and applied indoleacetic acid was car-

¹ Received for publication June 2, 1942.

The writer takes great pleasure in acknowledging the suggestions and criticisms offered by Professor J. P. Bennett, of the University of California, in whose laboratory this work was done. Thanks are also due to Mr. C. L. Dibble for technical assistance in carrying out the *Avena* tests.

ried out with 95 per cent methanol in soxhlet flasks. Extractions usually proceeded for twenty-four or forty-eight hours and were repeated until no further measurable amounts of auxin were yielded. The alcoholic extracts were evaporated to dryness on a steam bath assisted by an air blast. The dry residue was dissolved in 2 to 5 cc. of water on a steam bath for ten to twenty minutes, and the solution was mixed with an equal volume of 3 per cent agar. The agar gel was applied to the coleoptiles in blocks $2 \times 2.7 \times 1.7$ mm. = 14.3 mm.³ in size. One cc. of this gel corresponded to 0.5 to 1.5 gms. of fresh weight of extracted twig tissues. Water, acetone, ethyl-ether, 95 per cent ethanol, isopropyl alcohol, ethyl-acetate, ethyl-methyl-ketone and benzol also were found to extract auxin from resting twigs but were not used in the experiments reported.

TRANSPORT OF THE NATIVE AUXIN OF APPLE AND PEAR TWIGS.—The term native auxin in the present study applies to the naturally occurring auxin obtained from tissues by diffusion or by extraction with solvents. These extracts may possibly contain a mixture of several auxins. Free diffusible auxin was obtained from woody twigs by sandwiching sections 0.5 to 1 cm. long between agar blocks for two to twenty-eight hours. The agar blocks were then tested for auxin. These tests showed that young green twigs often (in six out of fourteen tests) contained appreciable amounts of auxin yielding curvatures of 1.5° to 11.4° . This auxin was transported basipetally, and no movement could be detected in the opposite direction (see table 1). Thus, the trans-

TABLE 1. *Auxin diffused into agar blocks from apical and basal ends of actively growing twig sections 1 cm. long. Diffusion for $2\frac{1}{2}$ to 3 hours at 25°C .*

Plant	Average <i>Avena</i> curvature caused by auxin diffused out from one section through	
	Apical end	Basal end
Hardy pear	0°	10.9°
	0	6.1
	0	7.0
Gravenstein apple	0	11.4
Grape vine	0	0.9
	0	0.8
Tobacco	0	5.6

port of the native auxin in young, actively-growing twigs is wholly or preponderantly polar. This does not necessarily exclude acropetal movement of auxin by way of the transpiration stream (see Hitchcock and Zimmerman, 1935, and Skoog, 1938). When the same tests were performed with the resting apple and pear twigs, no measurable or significant curvature of coleoptiles was obtained in the majority of cases. This was true for either the agar blocks placed at the apical end of the sections or those placed at the basal end. Occasionally a few blocks

in a set caused a negative curvature of 1 to 3° , but the average curvature for these sets was below 1° and not significantly different from 0° .

Although resting twigs usually do not contain measurable amounts of diffusible auxin, they nevertheless possess the mechanism for transporting auxin polarly, e.g., basipetally. This is shown by the following experiment. Agar blocks were applied to sections of young, actively-growing Gravenstein apple twigs, and the blocks now containing free diffusible auxin were applied to sections of resting Gravenstein twigs. Half of the auxin-loaded blocks were applied to the apical ends of the sections and the remaining applied to the basal ends. At the same time plain agar blocks were placed at the opposite ends of all sections to collect any transported auxin. After four hours the auxin content of the agar blocks was determined. The results were as follows:

	Average curvature
Agar blocks at basal end of sections—auxin applied to apical end.....	5.2°
Agar blocks at apical end of sections—auxin applied to basal end.....	0°
Agar blocks containing auxin but not applied to sections	4.6°
Check—Plain agar blocks on both ends of sections	0°

The auxin in the blocks applied at the apical end of the twigs was transported basipetally, but no detectable amount was transported in the opposite direction. This is not necessarily a proof of the complete absence of acropetal, apolar, movement of native auxin in the twig sections, since, when auxin was applied to the basal ends of the sections, an apolar transport by diffusion must have taken place through the dead lumina of the conducting system.

TRANSPORT OF INDOLEACETIC ACID.—Experiments similar to those described above were performed with agar blocks containing indoleacetic acid instead of native auxin. The results are presented in table 2.

It must be borne in mind, when evaluating the data in table 2, and other tables, that average *Avena* curvature of less than 1° can hardly be considered significant. Such values are designated by 0 in table 2. The sensitivity of the *Avena* test was such that 0 to 0.5° of negative curvature corresponded to approximately 0.01 p.p.m. indoleacetic acid in the agar blocks applied to the coleoptile. Therefore a "0" curvature in table 2 does not necessarily indicate that no indoleacetic acid was transported; but rather that if any was transported it was not in excess of approximately 0.003 γ per twig section.

Basipetal transport was indicated in twenty-six tests, of which only five showed significant transport in the opposite direction. In the latter tests the amount of auxin transported basipetally was three to thirteen times as large as that transported acropetally. It is reasonable to assume that the apolar auxin transport would be equal in both directions under the same conditions, because it is governed chiefly by diffusion. In the above-mentioned tests the apolar

TABLE 2. Basipetal and acropetal movement of indoleacetic acid through sections of resting apple and pear twigs. Sections were 5 mm. long, and transport lasted from two to sixteen hours at 25°C. Indoleacetic acid was applied in agar blocks either at the basal or the apical ends of the section.

component of the basipetal transport could not be measured directly, but was presumably equal in magnitude to the acropetal transport. Hence the difference between the total basipetal transport and the acropetal transport represented the polar transport. The ratio of the polar to the apolar transport in these experiments varied between 2 and 12. It is impossible to evaluate the ratio in those tests in which no significant curvature was obtained for the acropetal transport on account of the limit of the sensitivity of the *Avena* test. It is very likely that in these cases the ratio might be larger than that given above. But the five above-mentioned cases suffice to show that, at least in some instances, the basipetal transport of auxin in resting woody twigs may be no more than three to six times as large as the acropetal transport.

Similar results were obtained when the following experiment was carried out. Resting twigs were cut into 5 or 10 mm. long sections, immersed in indoleacetic acid solutions for two days at 2 to 5°C. The sections were then removed from these solutions, dried with filter paper, and agar blocks applied to both apical and basal ends. The whole was then placed at 25°C. in a saturated atmosphere for two to six hours, the agar blocks removed and tested for indoleacetic acid. The results of these tests are presented in table 3. Here, too, it is shown that when the twigs were immersed in solutions of low concentrations (0.1 and 0.133 p.p.m., respectively) no appreciable amounts of indoleacetic acid diffused out either through the apical or the basal ends. With higher concentration (0.2 and 0.4 p.p.m.) substantial amounts of indoleacetic acid passed out through

TABLE 3. *Indoleacetic acid diffused out of apical and basal ends of resting twig sections immersed for forty-eight hours in solutions of indoleacetic acid in cold storage. Period of diffusion two to four hours. Sections 5 or 10 mm. long.*

the basal ends of the twigs, but little or none out of the apical ends. Finally with still higher concentrations (0.8 and 4.0 p.p.m.) copious diffusion of the auxin took place from both the apical and the basal ends; indeed, when the initial concentration of the indoleacetic acid solution in which the twig sections were immersed was 4.0 p.p.m., the amount of indoleacetic acid diffusing out through the apical ends was even slightly in excess of that obtained at the basal ends. At least part and perhaps all of the auxin diffused out may have come from the conducting system of the twigs.

Thus, unlike the native auxin in which case only basipetal movement could be detected, the transport of applied indoleacetic acid in resting pear and apple twigs took place both basipetally and acropetally. Although the basipetal transport is faster than the acropetal one, when the auxin is applied at low concentrations, it is not necessarily so at high concentrations. The ratio of the amounts of indoleacetic acid carried basipetally to that transported acropetally may be dependent not only on the twig material used but also on time of diffusion and auxin concentration. The data on hand, however, are inadequate to establish any possible quantitative relations between these factors. Whether or not such relations exist in the case of the native auxin could not be ascertained, because all of the tests carried out with this auxin involved low concentrations of this substance, in which case only the basipetal transport could be detected.

Acropetal transport of indoleacetic acid in coleoptiles and pea shoots previously reported by various investigators was criticized (Went and Thimann, 1937, p. 100-101) on the ground that such a transport was observed only when the concentration of applied auxin was very large (a hundred or thousand-fold of that existing in the tissues), and that, therefore, such findings had no bearing on the normal transport of auxin. It is shown in table 2 that

appreciable acropetal transport of indoleacetic acid was observed in five cases, of which two occurred at a concentration of 0.1 p.p.m. of indoleacetic acid in the applied agar blocks, e.g. 0.0038 γ auxin applied per twig section, which amount yields a coleoptile curvature of approximately 14°. Actively-growing twig sections of the same size excreted native auxin during two to four hours in amounts which yielded curvatures up to 11.4° per section; this corresponds to approximately 0.002 γ . Mirov (1941) working with sections of pine twigs and using a similar technique observed curvatures as high as 18°, corresponding to 0.003 to 0.004 γ indoleacetic acid per section. Czaja (1934), employing an auxin test less sensitive than the standard *Avena* test, obtained from apical internodes of etiolated shoots of woody plants curvatures up to 23° per 5 mm. long sections. Hence, the amount of indoleacetic acid applied in the above-mentioned experiments in which acropetal transport of indoleacetic acid was observed is decidedly within the range of "physiological amounts"² of auxin, insofar as it may be compared with the native auxin on the basis of degrees of *Avena* curvatures.

It is evident from table 2, however, that when indoleacetic acid was applied in physiological amounts, e.g., in concentrations of about 0.2 p.p.m. or less, often no transport of auxin through the twig sections could be detected in either direction. It was found that under such circumstances a substantial part of the applied auxin was lost from the agar block containing it. This took place both at the apical and the basal ends of the twigs. Part of this auxin could be recovered from the sections by extraction with 95 per cent methanol, but the recovery was short of 100 per cent. In at least one instance, however, appreciable amounts of indole-

² The term "physiological amounts" of auxin, as used in this paper, applies to the amount of the naturally occurring auxin in plant tissues, obtained by diffusion from such tissues.

^a Values in this test were corrected for acropetal transport which amounted to 1.3–1.6° per section.

ing Hardy pear twigs, which yielded no diffusible native auxin. Twig sections 5 mm. long were divided into two lots. Agar blocks containing indoleacetic acid were placed at the apical ends and plain agar blocks at the basal ends of one lot of sections. The sections of the other lot were separated into bark and wood with as little injury to the bark as possible. The bark was rolled and held together by rubber bands. The wood and bark were then treated separately with agar blocks in the same manner as the intact sections; after a period of diffusion of four or five hours at 25°C. in a moisture-saturated atmosphere, the agar blocks at the basal ends were removed and examined for auxin. In another series of tests, resting Hardy twigs were cut into 5 mm. long sections, which were immersed for two days at 0°C. in solutions of indoleacetic acid of varying concentrations. The sections were then removed, dried with filter paper, divided into two lots and treated like those of the previous tests. The results of the two series of tests are presented in table 4. It was found that, after immersion in 4.0 p.p.m. indoleacetic acid, significant amounts of the auxin diffused through the apical ends. This diffusion represents the non-polar component of the transport; hence, the values of the basal agar blocks were corrected for this non-polar transport, and the corrected figures are presented in the last column of table 4. No measurable diffusion from apical ends occurred with the lower concentrations of indoleacetic acid.

It is evident from this table that: (a) basipetal transport took place in both bark and wood in three out of four sets of twigs. The reason for the lack of significant auxin transport in the sets of column 3 when bark and wood were examined separately is not known; (b) in all tests the amount transported through the wood was larger than that transported through the bark, although the cross section area of bark and wood was nearly equal. This may be at least partly due to the more extensive injury sustained by the bark during the process of peeling and subsequent handling, despite all precautions taken; (c) the sum of auxin transported through the separated bark and wood is smaller than that transported through the intact twig sections. This may also be the effect of injury; (d) it is also clear that the cambium cannot be the sole path of transport, if it transports auxin at all, since the wood sections which transported a fair fraction of the auxin were scraped thoroughly and were, no doubt, free of cambium.

These findings are contradictory to those of Cooper (1936) who concluded from the rooting response of ringed citrus cuttings to applications of indoleacetic acid that the latter moves only, or mostly, in the phloem. Cooper's data, however, are indirect and may be interpreted as showing that "rhizocaline," rather than heteroauxin indoleacetic acid, is not transported in the xylem. The present results are also at variance with the observations of Söding (1938), who found that the diffusate from bark or wood from twig sections, which had the cambium

scraped off, or water extractions of scrapings from wood and bark produced little or no curvature of *Avena* coleoptiles, while cambium scrapings gave pronounced curvatures. He concluded that cambium (and possibly also the adjacent young xylem or phloem tissues) is the sole path of transport of auxin in woody stems. It is not necessarily true, however, that the presence of a substance in a given tissue indicates that it is transported through that tissue. It might be merely accumulated there. Further, Söding states that the auxin he obtained from cambium scrapings represented a water extract of the tissue, rather than free diffusible auxin. It might have included chiefly auxin liberated from crushed or dead cells.

EFFECT OF STEAMING AND ETHERIZATION ON TRANSPORT OF INDOLEACETIC ACID.—Polar transport in coleoptiles is associated with activity of living cells. It is reversibly inhibited by exposure of coleoptile sections to ether (van der Weij, 1934, Clark, 1938). The effect of etherization and killing of woody sections by boiling or steaming for twenty to forty minutes upon transport of indoleacetic acid was determined as follows. Twig sections, approximately 5 mm. long, were placed in a moist chamber containing an open vessel of ether for sixty to ninety minutes at 25°C. Agar blocks containing indoleacetic acid were then applied to either the apical or basal ends and plain agar blocks to the opposite ends. After additional exposures for two to five hours to saturated ether vapor at 25°C. the originally plain agar blocks were examined for indoleacetic acid. The results are presented in table 5. In four of the six etherization tests basipetal transport substantially exceeded acropetal transport. In one it was completely inhibited and in another, for reasons unknown, acropetal exceeded basipetal movement. The partial pressure of ether in the moist chamber was approximately three times as high as that found by van der Weij (1934) to completely inhibit polar transport in coleoptile sections. The incomplete inhibition of polar transport in woody twigs as contrasted with that of coleoptiles may be due to incomplete permeation of the twig sections with ether, although some loss in "semipermeability" of twig tissues was indicated by diffusion of brown pigments from the twigs into the agar blocks. It is not known to what extent the injury by ether was reversible.

Steaming or boiling, however, completely inhibited polar transport in five out of six tests, and only in one test a slight, and perhaps an insignificant, portion of the polar transport persisted. But neither etherization nor steaming had consistently altered acropetal (apolar) transport as compared with the corresponding transport through non-treated sections.

The data in table 5 indicate that polar transport in resting pear and apple twigs is, like that in coleoptiles, carried out by living cells, and by its very polar nature cannot be ascribed to free diffusion.

THE MECHANISM OF APOLAR TRANSPORT OF INDOLEACETIC ACID IN TWIGS.—Diffusion may play only a

TABLE 5. *Effect of etherization, steaming and boiling of apple and pear twig sections on polar and apolar transport of indoleacetic acid.*

minor role in the movement of auxin inside living cells or across their membranes but must be an important factor in the transport of auxin through lumina of dead cells and cell walls. There is, therefore, good reason to assume that the apolar auxin transport in woody twigs is governed by diffusion. On the other hand, there is evidence to show that apolar transport of indoleacetic acid in woody twigs is not solely a process of *free* diffusion, but that other factors operate to modify this process. This is demonstrated by the following experiment.

Three grams of resting Hardy twigs were cut into 2mm. long sections and soaked overnight at 13°C. in 10 cc. of 0.24 p.p.m. indoleacetic acid. The sections were then removed from the solution and the indoleacetic acid, extracted in a soxhlet by 95 per cent methanol, was determined, as well as the residual concentration of the auxin in the solution. The latter was 0.15 p.p.m. The amount of indoleacetic acid extracted from the sections was, after correction for the native auxin extracted from sections soaked in distilled water, 0.27 p.p.m. expressed on fresh weight basis or 0.52 p.p.m. on the basis of the water content of the sections. If it be assumed that all the auxin absorbed by the tissues was present in them as free indoleacetic acid, then the concentration of auxin in these tissues was approximately 2 to 3½ times larger than in the surrounding solution, which is incompatible with free diffusion. The accumulation of indoleacetic acid in the sections can be explained, however, on the assumption that most of the auxin taken up by the tissues was re-

tained in living cells or was otherwise combined or adsorbed.

This assumption was substantiated by results obtained in another experiment in which a solution containing two parts per million of indoleacetic acid was passed from the apical ends through three-internode lengths of resting Hardy twig sections. Suction was applied at the basal end for 1½ to 2½ hours. Five cc. of solution, equivalent to 10 γ of indoleacetic acid, were forced through each section. Distilled water was then passed through the twigs in order to flush the conducting system free of auxin. The twigs were then extracted with 95 per cent methanol in soxhlet flasks until no more indoleacetic acid was obtained. The indoleacetic acid in these extracts, after correction for the native auxin extracted from check twigs injected with distilled water only, represents the amount of indoleacetic acid retained by the twigs either through adsorption, cell absorption, or by other means. Another set of twigs was steamed for thirty minutes prior to infiltration with indoleacetic acid, but otherwise was treated in the manner described above. The results were as follows. The auxin extracted per gram of tissue—reckoned as indoleacetic acid—was 0.04 γ for the twigs treated with water only, 0.40 γ for the steamed (dead) and 2.1 γ for the non-steamed (living) sections. Thus, both dead and living twigs possess a high capacity for retention of indoleacetic acid, but that of the living twig is several times larger than that of dead twigs.

In dead tissues accumulation of *free* indoleacetic acid in cells against a concentration gradient, as may

occur in living tissues, is ruled out. The retention of indoleacetic acid by steamed twigs must then be due in large measure to fixation of auxin in a water insoluble form. Skoog and Thimann's data (1940) suggest that proteins may act as auxin binders. Not all the indoleacetic acid penetrating the sections is necessarily fixed, however, and twigs to which this acid is applied through agar blocks, or by soaking in indoleacetic acid solutions, yield some diffusible auxin, provided enough of it is added, as indicated in tables 2 to 5.

The facts presented in this study can be explained by assuming that resting and possibly also actively growing twigs can absorb and transport indoleacetic acid apolarly, that is, both basipetally and acropetally, the direction of transport being determined by the concentration gradient. This is accomplished mainly by diffusion, which is, however, modified by fixation of the auxin along its translocation path. In addition to this mode of translocation there exists also a mechanism transporting indoleacetic acid in the basipetal direction only. This is the polar transport. Under the conditions studied both modes of transport operated simultaneously, the polar movement of the auxin being superimposed on that of diffusion.

In the experiments reported in this study polar transport was represented by the difference between the indoleacetic acid transported or absorbed basipetally and that absorbed or transported acropetally. Unlike coleoptiles apolar transport of this auxin in resting woody twigs can account for a substantial fraction of the total indoleacetic acid transported, when the latter is applied in concentrations of the order of 1 to 10 p.p.m. and may even obscure the polar transport (see table 3). The difference in behavior of coleoptiles and woody twigs may be at least partially accounted for by the difference in their anatomical structures; woody twigs contain many dead cells through which transport by diffusion can operate, while polar transport in coleoptiles, as well as in woody twigs, is carried out by living cells, in which *Avena* coleoptiles are proportionately richer than woody twigs.

While resting apple and pear twigs possess the capacity to transport indoleacetic acid acropetally and apolarly, in the experiments reported in this study transport was observed under artificial conditions. It is not known to what extent apolar translocation is a normal component of auxin transport in woody twigs.

SUMMARY

Non-resting, woody apple and pear twigs often contain free-diffusible auxin, while resting twigs rarely yield diffusible auxin in measurable amounts, although they contain appreciable amounts of auxin extractable with water, ether, acetone, methanol, ethanol, ethyl-acetate and benzol.

In non-resting twigs the movement of the native free-diffusible auxin in the direction of the long axis of the twig is mostly or entirely polar and basipetal.

In resting twigs native auxin externally applied by means of agar blocks was transported basipetally but no measurable transport could be detected in the opposite direction.

With indoleacetic acid applied by agar blocks in widely varying concentrations, basipetal transport was evident in twenty-six of thirty-four tests, while significant acropetal transport was indicated in six of the thirty-four tests. In two tests acropetal transport was observed when indoleacetic acid was applied in physiological amounts (0.1 p.p.m.). Basipetal transport of indoleacetic acid is more rapid than acropetal transport, but in five of the six above-mentioned tests the amount of the auxin transported basipetally was only 1 to 6 times as large as that transported acropetally, and in one instance it was of the same order of magnitude as basipetal translocation. This ratio is considerably smaller than that reported for *Avena* coleoptiles, for similar concentrations of applied indoleacetic acid.

Translocation of indoleacetic acid in sections of resting apple and pear twigs involves two simultaneously operating processes, namely polar transport and apolar transport. The polar transport operates basipetally only and is presumably carried out by living cells, being completely inhibited by steaming and partially inhibited by exposure to saturated ether vapor at 25°C. for several hours. The polar transport which operates both basipetally and acropetally is probably a diffusion process through the lumina of dead cells and through cell walls, but this process is modified by "fixation" or destruction of auxin along its diffusion path. A substantial amount, and sometimes all, of the "fixed" auxin can be recovered from the twigs by extraction with 95 per cent methanol.

Basipetal transport of indoleacetic acid and of the native auxin of pear and apple twigs takes place in both bark and wood. Available evidence does not indicate that cambium accounts for the bulk of basipetal transport of auxin, if it is involved in it at all.

CHROMOSOMAL EFFECTS OF LOW X-RAY DOSES ON FIVE-DAY TRADESCANTIA MICROSPORES¹

L. D. Marinelli, B. R. Nebel, N. Giles and D. R. Charles

PART I. EXPERIMENTAL²

ROENTGEN RAY effects on *Tradescantia* chromosomes have received increasing attention among geneticists since Sax (1938, 1939) demonstrated the possibility of obtaining quantitative results. In spite of the rapidly growing number of contributions which have appeared since (Darlington and Upcott, 1940; Fabergé, 1940a and b; Giles, 1940; Rick, 1940; Sax and Swanson, 1941; Newcombe, 1942a and b, and a summary by Sax, 1941), the literature still contains many contradictions, as well as a wealth of non-comparable data, which, as a whole, have not yielded to the scrutiny of a mathematical investigation. In the face of these shortcomings it was considered worthwhile to determine critically the limitations of the experimental method employed, as well as to relieve a somewhat confused situation by investigating rather closely two classes of aberrations only, and by restricting radiation dosage to the low range.

The present paper endeavors to present: (a) the relationship between effect and radiation intensity at constant dosage covering a range of 1 to 1000 (hereafter referred to as intensity experiment); (b) a series of experiments obtained from different x-ray apparatus and scored by different observers; these experiments were designed to show the variation of effect with radiation dose (to be called dosage experiments); (c) the statistical basis of sample size and of error estimates; (d) a unified mathematical interpretation which covers the dosage and intensity data of this paper as well as comparable data of the literature; and (e) morphological deductions and general predictions based upon the foregoing analysis.

MATERIAL AND METHODS.—Plants of a clone of *Tradescantia canaliculata* Raf. (*T. reflexa* Raf.) were grown in pots at Geneva, New York, using anthers from uncut plants for observation. Plants of

the same clone were grown in the garden of the Carnegie Institution of Washington at Cold Spring Harbor, New York. All data derived from the latter plants are from cut flower heads taken as follows: Inflorescences with six-inch stems were taken from the garden a short time (at most two to three hours) before irradiation, labelled with serial numbers and distributed at random in groups of twelve into four sample vials and one control, all vials being filled with spring water. The material was rayed during interphase previous to the onset of nuclear enlargement (cf. Sax, 1938). During irradiation the plants and cuttings were kept fresh by means of wet toweling and returned to the vials immediately after irradiation and kept in this manner until each experiment was completed. In all cases smear preparations were made on the fourth and fifth day. The material was fixed on the slide with 3:1 alcohol acetic acid, stained with aceto carmine and mounted in Zirkle's fluid. The dosage data were taken by separate and, in part, independent observers from radiation supplied by different x-ray machines. Variation in the climatic environment, the use of two distinct clones of plants, and a comparison between cut and uncut flower heads did not materially alter the results under investigation. Certain inconsistencies in the literature, as well as in the present data, are not believed to be due to any one of the three factors mentioned above.

The data are tabulated according to investigators, and time and place of the experiments. The Wilson-Geneva data (table 1) are from plants rayed at Geneva grown in an "uncontrolled" greenhouse during January and February 1940.

The Nebel-Geneva data (table 2) were obtained in the same way except that for six days preceding and during the experiment the plants were grown in a climostat at 70°F., and 50 per cent humidity, being exposed twelve hours daily to the light of ten lamps. The average intensity of illumination was 0.6 lumens per square centimeter.

The Sax (Nebel-Geneva) data (table 3) were derived from cut plants rayed and prepared at Harvard by Dr. Sax, scored by Nebel at Geneva.

¹ Received for publication May 25, 1942.

Approved as Journal paper no. 488 by the Director of the New York State Agricultural Experiment Station, Geneva, New York, May 15, 1942.

² By B. R. Nebel, N. Giles and L. D. Marinelli.

The Nebel-Cold Spring Harbor data (table 4) are from cut heads rayed at Memorial Hospital in New York and counted by Giles in New Haven and by Nebel in Geneva.

The intensity data (table 5) were collected by Giles and Nebel from cut heads rayed at Memorial Hospital, at intensities ranging from 1.25 to 600 r/m; the dose at the highest intensity was administered by Mr. F. Exner, at the Presbyterian Hospital of New York. Each observer scored part of the total number of slides for each point in the experiment. The conditions of irradiation were unknown to the observers until after scoring had been completed.

Uniform score sheets were used by each observer who compiled complete records of all observations for every cell observed. Observations were made at metaphase and anaphase. Aberrations were classified as dicentrics (D.), rings, both centric and acentric (R.), rods, isodiametric fragments, minute fragments, and notches or achromatic spots. Rods related to dicentrics and rings were not used in the present compilation. Rods representing terminal deletions are extremely rare in five-day material and were thus omitted. Chromosome notches were also omitted. Tricentrics were scored as two dicentrics. Rings were recorded as centric or acentric, but only those

structures were thus classified in which the lumen of the ring was clear, solid structures falling into the category of isodiametric fragments. For the present paper, dicentrics, centric rings and acentric rings were counted in one category which will be referred to as D.R. The isodiametric fragments (I.F.), corresponding to the interstitial deletions of Sax, are solid chromatic pieces without a lumen, globular or roughly cubic in shape, ranging in diameter from that of a chromosome to that of a half-chromatid. The isodiametric fragments listed in the case of the intensity experiment, include all size classes; i.e. they comprise also minute fragments which, in the case of the data on varying dosage, are omitted. The counts are expressed as aberrations per cell or, when comparison with theory is needed, as per cent aberrations per chromosome.³

Roentgen radiation was applied as follows: In Geneva a General Electric bedside unit operating at approximately 70 kv and 3 milliamperes with a tungsten target Coolidge tube, air cooled and capa-

^a Continuous irradiation.

ble only of intermittent service—one minute on, one minute off—was used.

In New York City three sources of x-rays were used, as follows: The intensity of 600 r/m was obtained by placing the material at 15.6 cm. from the anodes of two x-ray tubes operating at about 190 kv. The filtration was 0.5 mm. Cu + 1.65 mm. of Al and H.V.L. of the radiation was found to be 0.8 mm. of Cu. The intensities of 150, 50 and 20 r/m were obtained by using only one tube of the installation at distances of 22.1, 38.2 and 60 cm. from the anode. The intensities ranging from 1.3 to 10 r/m were obtained from a constant potential machine operated at 200 kv, 4 and 8 ma current, filter of

2.11 mm. Cu at distances 50.8 and 101.6 cm. from the anode. Both installations were at Memorial Hospital and have been described elsewhere (Marinelli, 1941). The x-ray output was determined directly with a thimble chamber which had been previously calibrated against a standard ionization chamber (Quimby, et al, 1938). The material was placed on a celluloid sheet 0.25 mm. thick with light wooden supports, and it was, in all cases, sufficiently removed from objects which may have scattered or absorbed x-rays.

The third source of radiation was furnished by Mr. F. Exner, Department of Cancer Research, Columbia University. This high voltage unit oper-

ated at 475 kv equivalent constant potential 16.5 ma, .25 mm. Cu plus .45 mm. Al filters, delivering 1260 r/m at 37 cm. focal distance with absorption and scattering corrections negligible; copper H.V.L. 2.8 mm.

PART II. STATISTICAL⁴

In advance of the intensity experiments it was uncertain whether the effect of a given dose should be gauged by (a) examining several hundred cells from a single flower head or by (b) examining fewer cells from each of a number of flower heads. A working answer was reached by the following considerations.

Suppose that N cells are examined from each of n flower heads, and that X aberrations of some particular kind are found altogether. The mean number of aberrations per cell, \bar{x} , is X/Nn . Repeated samplings of the same sort would be expected to yield somewhat different means with a standard deviation (i.e. standard error of the observed mean) of the value

$$\epsilon_{\bar{x}} = \sqrt{\frac{\bar{x}}{Nn} + \frac{\sigma_H^2}{n}} \quad (1)$$

The term \bar{x}/Nn represents the variation attributable to sampling errors, that is, the variance which would be expected in repeated samples of Nn cells from essentially similar flower heads. This follows from the fact that the array of numbers of cells with various numbers of aberrations in any one experiment is, at least approximately, a Poisson distribution.

The term σ_H^2/n represents the variation attributable to differences among heads in respect to effect of a given x-ray treatment. It is the variance of \bar{x} values which would be expected in repeated very large samples each from n heads among a population of flower heads which were not alike in reaction to identical treatment.

Given that it is not practical to use more than about six flower heads per experiment, how many cells should be counted per head? The answer depends primarily upon the degree of accuracy required, i.e., on the desired value of the ratio $\epsilon_{\bar{x}}/\bar{x}$. For this ratio equal to or less than some fraction $1/r$,

$$N \geq \frac{1}{\bar{x} \left[\frac{n}{r^2} - \left(\frac{\sigma_H}{\bar{x}} \right)^2 \right]}$$

It was estimated that under the conditions of the intensity experiments (table 5) \bar{x} and σ_H/\bar{x} would be respectively greater and less than 0.2. Then for the observed D.R. values to be at least six times their standard errors, i.e., for $r = 6$,

$$N \geq \frac{1}{.2 \left[\frac{6}{6^2} - .2^2 \right]} = 40.$$

⁴ By D. R. Charles.

Accordingly forty or more cells from each of about six flower heads were examined in most of the intensity experiments.

Actually \bar{x} was between 0.35 and 0.55 in twelve of the fourteen experiments, and σ_H was found to be negligible. So the accuracy obtained was nearly twice the minimum set *a priori*: the D.R. values of table 5 are on the average 11.5 times as large as their standard errors.

In table 6 evidence is presented that inter-head variation of x-ray sensitivity is negligible. Column A is the standard deviation of D.R. means within successive experiments of table 5, calculated in the usual way from the three-to-eight head means within each experiment. Column B is the standard deviation to be expected from equation (1) if σ_H is practically zero, i.e. if the inter-head differences in D.R. means are attributable completely to sampling error. For this standard deviation among one-head samples the formula becomes $\sqrt{\bar{x}/N}$.

TABLE 6.

Int.	A	B	Int.	A	B
1.25	.069	.069	5	.060	.093
2.5	.046	.074	10.2	.099	.088
5	.096	.081	20.5	.130	.082
			50.1	.154	.083
50	.182	.098	600	.119	.102
154	.074	.107	618	.071	.102
150	.103	.086	1200	.073	.115
616	.042	.083			

Since the predicted standard deviations are higher than the observed (i.e. account for even more variation than is observed) in six of the fourteen experiments, there seems to be no reason for assuming any significant sensitivity difference between heads under the conditions of these experiments.

PART III. MATHEMATICAL INTERPRETATION⁵

Before entering into a mathematical approach to this problem, it may be well to notice that, as shown in table 7, the ratio I.F./D.R. is constant within the limits of experimental error throughout the experiments herein reported.

TABLE 7.

Experiment	Ratio I.F./D.R.
Nebel-Geneva	1.66 ± 0.15
Wilson-Geneva	1.21 ± 0.28
Nebel-Cold Spring Harbor	1.48 ± 0.26
Intensity data	1.57 ± 0.11
Sax, Harvard	1.46 ± 0.32
General average	1.48

The change in the I.F. classification already mentioned in Part I affects the I.F. to D.R. ratio by amounts which, in comparison to the average devia-

⁵ By L. D. Marinelli and B. R. Nebel.

tions, are too small to invalidate the above mentioned conclusion. It is obvious, therefore, that any mathematical expression which is adequate for the quantitative description of the D.R. phenomenon will become adequate also for the I.F. description by the mere use of a constant factor equal to 3/2; the interpretation of this factor will be left temporarily in abeyance.

If one supposes that the D.R.'s are the result of two independent events (chromosome breaks) which are reversible in some fashion (chromosome restitution), the analysis of both Swann and Del Rosario (1931) and Lea (1938) can be applied directly. Although these analyses differ only in their assumption as to the mode of recovery, their application to the data on hand will be treated separately and in reverse chronological order for reasons which will soon become obvious.

Lea's analysis is developed from the assumption that a single break fails to produce a D.R., but a second break (within definite space limits), happening within time T of the first, produces the effect. Elapse of a time greater than T between the breaks presupposes complete restitution of the first break and consequently failure to produce a D.R. In order to comply with the intensity data, however, it has been found necessary to modify slightly Lea's assumption, in that only a fraction K of these restricted double breaks are effective in producing D.R.'s.

Let N be the radiation intensity and let it be defined in terms such that Ndt is the probability of causing a break in any one chromosome in time dt ; then, according to Lea, the number of D.R.'s present per chromosome can be expressed as:

D.R./chrom. =

$$K \left\{ 1 - e^{-Nt} \left[1 + Nt + \sum_{s=2}^{\infty} \frac{(Nt)^s}{s!} \left(1 - \frac{(s-1)}{t} T \right)^s \right] \right\} \quad (1)$$

In this formula t is the irradiation time and the summation extends over integer values of S from $S = 2$ to $S = t/T + 1$. By suitable graphical analysis it is possible to reproduce the intensity data (table 5) with the following constants:

$$Nt = \frac{\text{Dose in r}}{60} = \frac{300}{60} = 5; \quad T = \frac{60}{9} = 6.7 \text{ minutes}; \\ K = 0.0786.$$

The results of the calculations are shown in the third column of table 8. It must be noted, however, that when these values of T and K are used in (1) in conjunction with the values of Nt proper to the x-ray doses used in the rest of the experiments, Lea's formula fails to produce satisfactory agreement with the experimental data.

According to Lea's formula "absolute saturation" would take place at 300 r when delivered at rates higher than 50 r/m. In other words, formula (1), in order to conform to the intensity data (table 5), sets a maximum on the number of aberrations that can be produced by any dose of x-rays, however

TABLE 8. Comparison between intensity experiment and theory. Dose = 300 r.

r/m	Exp.	% D.R./chromosome	
		Formula (1) $T = 6.7 \text{ min.}$ $K = .0786$	Formula (7) $N = 1/640$ $\times r/m$ $\lambda = 0.02$
1.25	3.22	3.2	3.12
2.5	4.78	4.5	4.62
5.0	5.77	5.8	5.95
10.0	5.8	6.9	7.12
20.0	7.1	7.6	7.44
50	8.0	7.8	7.83
150	7.8	7.8	7.99
600	8.7	7.8	8.10
1200	9.0	7.8	8.10

high. This maximum is only 7.86 per cent of the total number of chromosomes (0.46 per cell), and it is in obvious contradiction to experimental evidence.

In order to avoid this difficulty and to retain the assumption of a definite restitution time, it would be necessary to postulate that the probability N associated with any one chromosome break is not necessarily independent of either dose or time. This would require, however, a radical alteration of Lea's theory.

Swann and Del Rosario (1931) have considered the case where "two impacts of the sensitive region with an a particle are necessary to cause death of *Euglena* with a generality which allows for recovery of the cells between the two impacts."

Since it is anticipated that their theory will prove useful in explaining the existing data, it will be summarized here in some detail in terms that apply to chromosome aberrations. It will be assumed that:

(a) Chromosome breaks are produced at random by x-ray radiation at a rate proportional to the radiation intensity.

(b) The healing rate of singly broken chromosomes is numerically equal to a constant fraction λ of the total number of single breaks present.

(c) Dicentric and rings are the result of two chromosome breaks occurring within effective volumes " V_a "; the number of effective volumes V_a available is equal to the total number of chromosomes (n).

(d) I.F.'s are the result of two chromosome breaks occurring in effective volumes, V_b , which are not competing with V_a ; their total number is $3n/2$.

(e) Completed chromosome aberrations are irreversible.

It is realized that the description of the effective volumes is, from a realistic point of view, unsatisfactory, since the volumes are defined merely by their total number. A more satisfactory definition would have been possible if, for purpose of description, the scoring had been divided in isodiametric fragments and rings (involving presumably one

chromosome) on the one hand and dicentrics (involving two chromosomes) on the other.⁶

In considering the process of D.R. formation let:

t = the time of exposure.

n_0 = the number of V's in which no break has occurred or which have recovered from one.

n_1 = the number of V's in which one break has occurred and which have not yet recovered.

n_2 = the number of V's in which two breaks have occurred, namely the number of D + R.

N = the probability of causing a chromosome break within any one effective volume in unit time. It is assumed that this is proportional to the x-ray intensity and of the same magnitude for all single breaks.

The equations describing the process postulated above are:

$$\frac{dn_0}{dt} = -Nn_0 + \lambda n_1 \quad (2)$$

$$\frac{dn_1}{dt} = Nn_0 - \lambda n_1 - Nn_1 = -\frac{dn_0}{dt} - Nn_1 \quad (3)$$

$$\frac{dn_2}{dt} = Nn_1 \quad (4)$$

Summing (2), (3) and (4) term to term and integrating there follows:

$$n_0 = n - n_2 - n_1 \quad (5)$$

when the boundary conditions at $t = 0$ are taken into consideration.

By differentiating (4), multiplying (3) by N and taking into account (4) and (5) there results the

⁶ In any case it will be found useful to define the effective volumes so as to permit the use of a disposable constant coefficient; in the case of D.R. this factor need not be different from unity but in the case of I.F.'s it is assumed to be close to 3/2.

following ordinary linear equation of 2nd order in n_2

$$\frac{d^2n_2}{dt^2} + (2N + \lambda) \frac{dn_2}{dt} + N^2n_2 = N^2n$$

the general solution of which is

$$n_2 = n + A e^{-(\alpha - \beta)t} + B e^{-(\alpha + \beta)t} \quad (6)$$

where $\alpha = N + \lambda/2$ and $\beta^2 = N\lambda + \lambda^2/4$. After determination of A and B , subject to the boundary conditions $n_2 = 0$ and $dn_2/dt = 0$ at time $t = 0$, one obtains

$$n_2 = n - \frac{n}{2\beta} \left[(\alpha + \beta)e^{-(\alpha - \beta)t} - (\alpha - \beta)e^{-(\alpha + \beta)t} \right] \quad (7)$$

which is the desired relationship.

The adaptation of (7) to the intensity data was carried out by trial and error.⁷ By assuming

$$N = \frac{r/m}{640} \text{ and } \lambda = 0.02 \text{ (namely, 2 per cent of the}$$

broken chromosomes healing in one minute) good agreement was obtained with the intensity data. These values were obtained by equating expression (7) to the experimental results obtained at 5 r/m and 150 r/m which are the most reliable in the intensity experiment; the calculated values are shown in the fourth column of table 8. The data for varying doses at continuous irradiation (Nebel-Cold Spring Harbor, table 4) can be represented fairly well with the same formula and the same constants as shown in table 9.

⁷ The authors wish to thank Dr. Bertrand Goldschmidt of the Curie Laboratory, Paris, for his most generous assistance in the calculations necessary to this work.

TABLE 9.

t = 2 min. ; λ = 0.02		% D.R./Chromosome		
		Theoretical	Exp.	Theor./exp.
400 r	N = $\frac{200}{640}$	12.9	16.3	0.8
	N = $\frac{100}{640}$	3.9	4.3	0.9

TABLE 10. Comparison between formula (7) and Wilson-Geneva experiment.

$$N = \frac{r/m}{640}, \lambda = 0.02.$$

		% D.R./Chromosome		
Dosage in r	t min.	Exp.	Theor.	Theor./Exp.
660	11	21.3 (?)	26.3	1.23 (?)
550	9	20.8	20.4	.98
400	7	14.0	12.5	.89
300	5	9.2	7.85	.85
200	3	4.3	3.9	.91
100	1	1.13	1.1	.97

If $N = r \text{ m}/600$ the agreement would be better than 3 per cent at both dosages; this may mean a change of only 6.5 per cent in either radiosensitivity or in x-ray dose. Since the intensity data are the result of many more independent determinations of satisfactory accuracy, it is preferable to retain the constants as derived from them and to reserve final evaluation of N and λ by the method of least squares from different types of experiments whenever the nature of the problem will warrant it.

Formula (7) is in fair agreement also with the remaining dosage data herein presented. The magnitude of the experimental error, however, does not warrant at this moment a cumbersome extension of Swann's analysis to check the Wilson-Geneva and Nebel-Geneva dosage experiment with intermittent exposures, since in these the off-periods are too short to yield conclusive evidence on recovery. However, gross comparison between experiment and theory based on total time elapsed has been made, and the results are shown in table 10.

In search of further confirmation of Swann's formula, one finds also agreement by interpolation with that part of Sax's data (1941) which is to be considered as the most reliable, on account of explicit statements made about the calibration of the roentgen tube. Thus, in table 11 there is a comparison between his high intensity data (Sax, 1941) and theory with the same constants derived from our experiments.

In tables 12 and 13 the comparison is extended to Sax's dosage curves at 2.7 and 20 r/m. (Sax's table No. 6, 1941.)⁸

The rate of healing $\lambda = 0.02$ seems rather reasonable. Thus, according to this value, 90 per cent of the single chromosome breaks would heal within 115 minutes after their occurrence; this fact is not rigorously confirmed by direct evidence, yet it cannot be considered inconsistent with Sax's fractionation dosage experiments. It is unfortunate that the greater part of Sax's extensive data cannot be used in any crucial way to confirm or disprove Swann's theory; the numerical values available show both wide fluctuations and consistent differences with the values

TABLE 11. Comparison between formula (7) and Sax's data (1941).

$$\text{Radiation intensity} = 160 \text{ r/m}; N = \frac{r/m}{640}; \lambda = 0.02.$$

Dose in r	% D.R./Chromosome		Theor./Exp.
	Exp.	Theor.	
100	1.0	1.1	1.1
200	3.1	3.9	1.26
300	6.5	8.1	1.24
400	11.0	13.0	1.18

⁸ It is to be noted that the ratio between the theoretical values and Sax's (1941) is rather consistent for any given radiation intensity. The average ratio, (1.00 for table 12, 1.16 for table 13, and 1.19 for table 11) is seen to increase with the intensity of the radiation. This points to a small but definite difference in N of about 9 per cent which may be interpreted as above.

400	9.95	11.7	1.18
500	13.0	16.33	1.26

presented or used in this paper. This discrepancy cannot be due to differences in scoring methods, which are essentially identical. The only difference arises from the inclusion in scoring by Sax of only centric rings rather than of all large rings. However, a correction for this factor probably would not raise his absolute values by more than four per cent.

It seems more likely that most of the discrepancy is due to inadequate radiation dosimetry; the importance of this factor has been discussed by Fabergé (1940a) and need not be emphasized here.

The recovery mechanism embodied in assumption (b) could be brought to a more direct test by means of well planned experiments with fractional x-ray doses. The general solution (6) can be used to calculate the results to be expected from two doses Nt_1 and Nt_2 of x-rays administered t_p minutes apart.

It is obvious that the effect of the first dose is adequately described by (7); during the rest period t_p , $N = 0$, hence the fundamental equations become

$$\frac{dn_0}{dt} = \lambda n_1 \quad \frac{dn_1}{dt} = -\lambda n_1 \quad \frac{dn_2}{dt} = 0$$

which give immediately:

$$[n_2]_{t_p} = [n_2]_{t_1} \text{ and } [n_1]_{t_p} = [n_1]_{t_1} e^{-\lambda t_p} \quad (8)$$

where the subscript indicates the time interval t_1 , t_p or t_2 at the end of which n_1 or n_2 are calculated. In order to calculate the effect of the second dose delivered in time t_2 , the relationships (8) are used as boundary conditions to which (6) must conform

Thus at $t_2 = 0$

$$[n_2]_{t_2} = [n_2]_{t_1};$$

hence from (6)

$$A + B = -n + [n_2]_{t_1} \quad (9)$$

Moreover from (4)

$$\left[\frac{dn_2}{dt} \right]_{t_p} = N [n_1]_{t_1} e^{-\lambda t_p}$$

hence at $t_2 = 0$, from (6)

$$(a - \beta) A + (a + \beta) B = -N [n_1]_{t_1} e^{-\lambda t_p} \quad (10)$$

Since $[n_1]_{t_1}$ can be obtained by direct differentiation of (7), namely

$$[n_1]_{t_1} = \frac{nN}{2\beta} \left[e^{-(a-\beta)t_1} - e^{-(a+\beta)t_1} \right] \quad (11)$$

the result follows immediately in the form

$$[n_2]_{t_2} = n - \frac{1}{n} \left\{ (n - [n_2]_{t_1}) (n - [n_2]_{\text{exp.}t_2}) e^{-\lambda t_p} - [n_1]_{t_1} [n_1]_{\text{exp.}t_2} \right\} \quad (12)$$

where exp. t_2 indicates that t_2 is to be used instead of t or t_1 in the exponents of formulae (7) and (11); this conventional notation should not be confused with the one adopted previously.

In the particular case of equal irradiation time intervals, namely $t_1 = t_2 = t$, (12) reduces to

$$[n_2]_{t_2} = n - \frac{1}{n} \left\{ (n - [n_2]_{\text{exp.}t})^2 - e^{-\lambda t_p} [n_1]_{\text{exp.}t}^2 \right\} \quad (13)$$

It is evident that for $t_p = \infty$ the baseline as defined by Sax (1939, 1941) is

$$[n_2]_{t_2; t_p = \infty} = n - \frac{1}{n} \left[n - (n_2)_{\text{exp.}t} \right]^2 \quad (14)$$

and that the effect of the uninterrupted dose ($t_p = 0$) for time $2t$ is:

$$[n_2]_{2t} = n - \frac{1}{n} \left\{ (n - [n_2]_{\text{exp.}t})^2 - [n_1]_{\text{exp.}t}^2 \right\} \quad (15)$$

By subtracting (14) from (15) and solving for $[n_1]_{t_1}$, the number of single breaks existing at the end of the first irradiation, one obtains.

$$[n_1]_t = \sqrt{n \left\{ [n_2]_{2t} - [n_2]_{t_2; t_p = \infty} \right\}} \quad (16)$$

This expression indicates another convenient, though indirect, experimental check on the theory; namely although $[n_1]_t$ cannot be determined directly by observation (because of the recovery taking place between radiation of the material and observation of results), it can be calculated from experimental

values by means of (16) and compared with the theoretical predictions of (11).⁹

The recovery constant λ is also capable of direct experimental determination. In fact, when (16) and (14) are substituted in (13) one obtains

$$-\lambda t_p = \log \frac{[n_2]_{t_2} - [n_2]_{t_2; t_p = \infty}}{[n_2]_{2t} - [n_2]_{t_2; t_p = \infty}} \quad (17)$$

which shows that the semi-logarithmic plot of the fraction in the right hand term against the rest period t_p should be linear with a slope (independent of both time and dosage used in the irradiation) equal to the recovery constant λ . The experimental determinations of (16) and (17) are apt to be of little value unless the denominator of the right hand of (17) is sufficiently large. This requires high radiation intensities with short exposure time, fairly high dosage, and large numbers of chromosomes. Thus, if the radiation is administered in two doses of 200 r of one minute each, the number of per cent D.R. per chromosome will be 12.9 when $t_p = 0$ and 7.64 for $t_p = \infty$. The difference 5.26 represents a 40 per cent change in the total number of D.R.'s. Therefore, to obtain an accurate value of λ , the D.R. values for the intervening t_p 's must be known to within a few per cent.

The usefulness of the fractional method, however, will increase with higher radiation doses and with detailed aberration scoring. Its careful application will help to clarify the limits within which the simplified assumptions herein made are applicable, as well as to determine the possibility of a variation of the rate of recovery λ with dose, as suggested recently by Newcombe (1942b). It is anticipated that, apart from the latter phenomenon, provision may have to be made in Swann's theory to account for partial obliteration of two-break aberrations at higher doses, owing to the frequent occurrence of more than two breaks within the effective chromosomal volumes. It remains to be seen, also, whether aberrations are subject to the same probability of break (N not constant on account of chemical changes in chromosomal or cytoplasmic material), and whether reclassification of morphological processes is necessary to explain the aberration data that Newcombe and Fabergé have obtained at much higher x-ray doses.

GENERAL CONCLUSIONS.—The power law concept used so often in the literature dealing with the quantitative aspects of x-ray chromosome aberrations has not been helpful in interpreting the data on D.R.'s and I.F.'s, beyond the point of suggesting the possibility of their being caused by double chromosome breaks. Swann and Del Rosario's theory of recovery accounts for most anomalies in the data herein presented or reviewed. Rather simple calculations based on their formula will show, for instance, that the differences between experiments at

⁹ For all practical purposes $t_p = \infty$ is reached after about three hours.

constant intensity and those at constant time should exist at low but not at high x-ray intensities; they will show, also, that the time intensity factor at low doses, while not negligible, is nevertheless relatively less important than at higher doses.

Swann and Del Rosario's theory is a description of a morphological event of microscopic dimensions and requires no assumption as to the primary effect of x-rays on chromosomes or cytoplasm beyond the requirement that the rate of production of breaks be proportional to the x-ray intensity.

The evidence presented in this paper favors the type of recovery postulated by Swann and Del Rosario, namely that the probability of a single chromosome break healing in the next unit time is a constant λ independent of x-ray dose and of irradiation time. The type of recovery assumed by Lea, namely that restitution of chromosome breaks occurs within a fixed time, fails to conform with experiment.

The assumption of Swann's theory do not conform with Darlington and Upcott's (1940) interpretation of Sax's (1939, 1940) intensity experiments, namely with the hypothesis that during the first hour after breakage the proportion of breaks which are lost by restitution depends on the competition for reunion among broken ends at the time of splitting. This mechanism presupposes formation of D.R.'s and I.F.'s after cessation of irradiation (contrary to equation (4) which gives $dn_2/dt = 0$ for $N = 0$) and a dependence of the recovery probability λ of a fresh break on the number n_1 of the single breaks existing in the chromosomal material (contrary to Swann's assumption $\lambda = \text{constant}$). The hypothesis of Sax (1939), that in the course of time the first break may heal before a second break occurs in an adjacent chromosome, is consistent with the fundamental equations.

The foregoing mathematical interpretation at present is to be considered valid only for low doses of radiation, since it neglects the possible effects of radiation on the immediate environment of the chromosomes and ignores the possibility of loss of chromosome aberrations scored through overlap of events within the same chromosomal pieces.

SUMMARY

The quantitative data herein presented on the action of x-rays on chromosomes represent the results of a study carried out with standard material and equipment. Scoring of the aberrations produced has been obtained by independent observers, according to conventional terms and definitions. Experimental errors and the size of sample necessary for adequate precision have been determined from statistical theory.

The data herein presented, as well as the most recent data of Sax (1941), have been interpreted satisfactorily in the light of a theory presented by Swann and Del Rosario in their study of the effect of radioactive radiation upon *Euglena*. Moreover, an extension of this theory is presented to predict results to be expected from fractional x-ray doses, and suggestions are advanced as to the experimental prerequisites of these investigations.

THE SUPPLY OF WATER TO TRANSPIRING LEAVES ¹

L. G. G. Warne

THE MAINTENANCE of a favorable water balance in the leaves of transpiring plants demands that loss of water from the leaves shall not, except for very short periods, exceed the supply of water to them. The available balance of water in the leaves which can be expended in transpiration without the onset of wilting is surprisingly low in mesophytes (Knight, 1922). If, therefore, wilting and its consequences are to be avoided, a regular flow of water to the leaves is essential. With succulent plants, possessing special water storage tissue, the position is different, while with many non-succulent xerophytes a considerable reduction in the water content of the leaves may occur without damage to the leaf resulting. During its passage from the soil to the leaves, water first enters the root hair and then passes through the cortex, endodermis and pericycle to the xylem, in which tissue it is transported to the foliage leaves. At any stage in its transport the water may encounter resistances to its passage, the resistances varying in magnitude from plant to plant and probably from time to time within the same plant. It is the purpose of this paper to discuss the resistances offered to water transport by both root and stem and the mechanism by which these resistances are overcome.

STEM RESISTANCE.—Various determinations of the ability of stems to transmit water have been made (Dixon, 1914; Farmer, 1919; Warne, 1937), and it appears that the resistance offered to the movement of water in the vascular system of the stem is not great. Dixon with *Taxus baccata* showed that, to obtain a velocity of upward water transport in the stem sufficient to cover the transpiration requirements, needed a pressure equivalent to a head of water twice the length of the stem. If Dixon's conclusions are generally applicable, then in the tallest trees a pressure of approximately 23 atmospheres is necessary to raise water to the level of the highest leaves. The osmotic pressure of the leaves of trees is often sufficient to supply such a pull to the water column in the tracheae, while expressed plant saps are capable of transmitting a pull of this magnitude owing to their cohesive properties (Dixon, 1914). In shrubs and herbaceous plants the necessary pressure is much smaller. In a small shrub 200 cm. in height a pressure of only about 0.5 atmosphere is needed. Farmer (1919), however, showed that the conductivity of the woods of different species varied considerably. The specific conductivity, e.g., the amount of water transmitted through a 15 cm. length of stem in fifteen minutes under a pressure of 30 cm. mercury divided by the area of cross section of the conducting tract, was higher for deciduous than for evergreen trees and shrubs. The values found varied from 1.0 for *Ruscus aculeatus* to 95 for the

Osier (*Salix viminalis*). These data, however, are not easy to interpret. When considering the resistance offered by the stem to the flow of water to the leaves, it is desirable to take into account the area of transpiring foliage which has to be supplied. Specific conductivities alone may be misleading. A low specific conductivity may be more than counterbalanced by a large amount of conducting tissue or by a reduction in the transpiring surface. It seemed desirable, therefore, to determine conductivities of the shoots of a number of species and to express these conductivities on the basis of area of foliage to be supplied. This has been done, and different species are found to give values which vary widely.

Experimental.—Determinations have been made of the conductivities of the stem of a number of species and measurements of leaf area made simultaneously. The conductivity measurements have been made on two-year old shoots, and the total area of foliage carried by the shoot above the piece of stem used for the conductivity measurement has been determined. With one species, *Buxus sempervirens*, the amount of water transmitted through a two-year old stem was so small that older stems (four to five years) were used. All the material came from the University Experimental Grounds and so had been grown under uniform conditions of soil and climate. The apparatus and method used have been described in a previous paper (Warne, 1937). The data collected are assembled in table 1.

In column two are given data for absolute conductivities, or the amount of water in grams transmitted through a 15 cm. length of stem under a pressure of 30 cm. of mercury in fifteen minutes, while in column 3 the conductivities are expressed as grams of water per 100 square cm. of foliage carried by the

¹ Received for publication May 15, 1942.

My best thanks are due to Mr. A. D. Greenwood, B.Sc., who carried out the osmotic pressure determinations.

shoot. Usually about twenty determinations were made for each species. All the determinations were made during late summer when extension growth for the year had ceased but before leaf fall occurred.

Farmer (1919) found a lower specific conductivity in evergreens than in deciduous trees and shrubs. The data presented in the table also show a lower conductivity for the evergreens, although the conductivity here is expressed on the basis of area of foliage carried by the shoot.

Discussion.—The interpretation of the data presented is not easy. There is no doubt that the resistance offered to the flow of water to the transpiring leaves by the stems varies considerably from species to species, but whether the resistance is in fact a serious obstacle to the flow of water to the leaves is open to question. The data presented refer to the conductivity of 15 cm. pieces of stem, whereas in the intact plant not only is the conductivity of a unit length of stem important but it is necessary in considering stem resistance to take cognizance of the whole distance over which the water has to be transported. Of the species for which data are presented, the simplest case from this point of view is that of *Ruscus aculeatus*. The shoots of *Ruscus aculeatus* used in this work were all cut near ground level and the length of the shoot was from 50 to 60 cm. In *Ruscus* the diameter of the stem and probably also its conductivity does not diminish sensibly until the level of the lowest transpiring cladodes is reached, and above this point the diameter and conductivity probably decrease more or less in proportion to the decrease in the transpiring surface above any particular point on the stem. Hence, no very serious error is introduced if for a moment we look upon the stem as though it were of uniform diameter with all the transpiring cladodes aggregated at the apex. A pressure of 30 cm. of mercury is sufficient to cause water to be transmitted through a 15 cm. piece of stem at the rate of 0.055 gm. in fifteen minutes or 0.220 gm. per hour, equivalent to 0.172 gm. water per hour per 100 sq. cm. of cladode carried by the shoot. To transmit this amount of water through 60 cm. of stem requires a pressure of the order of 120 cm. of mercury (1.6 atmos. approximately). This supply of water barely equals the highest rate of transpiration recorded here for *Ruscus*. With cut shoots of *Ruscus* standing with their basal ends in water in a laboratory where the temperature reached 28°C. and in bright sunlight the mean transpiration rate recorded over a period of four hours was 0.208 gm. per hour per 100 sq. cm. of cladode. To cause a transmission of water at this rate a pressure of approximately 1.84 atmospheres is needed. This is greatly in excess of Dixon's estimate of the necessary pressure required for *Taxus baccata*. *Ruscus aculeatus*, however, is an extreme case. Not only has it the lowest specific conductivity of the species tested by Farmer (1919), but it has also the lowest conductivity per 100 sq. cm. of transpiring surface. On the other hand the distance over which the water has to be transported is relatively small in *Ruscus*.

Nevertheless, even in the extreme case of *Ruscus aculeatus*, the pressure needed to overcome the resistance of the stem to water transmission is negligible compared either with the pull that transpiring leaves can exert or to the tension which expressed plant sap is capable of transmitting. Stem resistance is likely to be of no greater importance in the other species, although in the other shrubs and trees, which are larger than *Ruscus*, water has to be transported over a greater distance but through wood with a lower resistance. A similar conclusion was reached as a result of an experiment of a different nature. Determinations were made of the transpiration rate from shoots of *Ruscus aculeatus* in which the length of the stem was varied so that the resistance offered by the stem to the flow of water differed in the different shoots used. The procedure adopted was to select shoots of *Ruscus* with at least 30 cm. of bare stem below the level of the lowest cladode so that about 50 per cent of the shoot consisted of bare stem.

Determinations were made of the transpiration rates of these shoots and also of shoots from which most of the lower bare stem had been removed, so that in the latter shoots the stem resistance had been reduced to a level considerably below its original value. The determinations were made by standing the shoots with their basal ends in water covered with a film of oil and weighing them at intervals of a few hours. Experiments of shorter duration were not considered desirable owing to the possibility that transpiration might take place over short periods, largely at the expense of the water present in the shoot. That this did not occur in the experiments is shown by the fact that the transpiration rates did not sensibly diminish over a period of four days, and during this period loss of water by transpiration greatly exceeded the total original water content of the cladodes. The results obtained were of an entirely negative character, and it does not seem necessary, therefore, to present them in full. Both under conditions favoring high transpiration (temperature 20°C. and bright sunlight) and low transpiration (dull and humid) there was no difference in the transpiration rates for the two sets of shoots. Removal of half of the stem with a consequent reduction in stem resistance did not effect any increase in the transpiration rate. This was so for shoots standing in water and, therefore, with a good water supply. Similar results were obtained for *Rhododendron ponticum*. It appears likely, therefore, that in the species tested here and probably in others also, the resistance offered by the stem to water transport does not constitute any serious obstacle to the flow of water to the transpiring foliage, at least when the supply of water to the shoot is optimal. These results are of special interest in view of the fact that Kramer (1938) found that removal of the root system did with some plants increase the transpiration rate and suggests that stem resistance may be of less importance than root resistance. When the water supply is poor, the additional resistance

to water flow offered by a stem of low conductivity may be of greater importance. The relation between low stem conductivity and the possession of evergreen xeromorphic foliage may well be more than coincidence. Although experiments have failed to show that stem resistance offers any serious obstacle to the flow of water to the transpiring organs, we cannot conclude that the stem of the evergreen of low conductivity could under all conditions transmit a sufficient amount of water to cover the requirements of a mesophytic foliage. In spite of the suggested unimportance of stem resistance, it is well known that the leaves of plants often do wilt when subjected to conditions favoring high transpiration even when the supply of water to the roots is good. It is likely, therefore, that other resistances to the flow of water to the foliage, more important than stem resistance, are operative.

ROOT RESISTANCE.—When a well watered, actively growing plant is decapitated just above the soil level, liquid frequently exudes from the surface of the cut stump. It is generally believed that the liquid is exuded from the cut ends of the xylem vessels and tracheids (Stiles, 1936; Kramer, 1940). That this is the correct interpretation of the phenomenon has been disputed (James and Baker, 1933). Not merely is liquid exuded, but considerable pressure (root pressure) may be set up. It is commonly assumed (Thomas, 1935) that in the intact plant the root pressure is such that water may be forced some distance up the stem so that the root system may be a positive aid to the upward transport of water in the plant. The data which will be presented here support the view that, at least under conditions favoring fairly high transpiration rates, it is more correct to look on the root system as constituting a resistance to the flow of water from the soil to the transpiring leaves.

Preliminary experiments.—When measurements are made of the rate at which liquid is exuded from the stump of a decapitated plant, it is found that this usually does not equal the rate at which water is lost by an intact plant in transpiration under normal conditions. A few data will illustrate this point. The transpiration determinations were all made by weighing potted plants at intervals, the pot being encased in a waterproof covering, under ordinary conditions in the laboratory. After a few hours the plants were decapitated, and the rate of exudation from the stump was determined.

In no case here is the exudation as great as the transpiration, while not infrequently no exudation occurs (Kramer, 1941). The root system alone,

therefore, does not exude sufficient liquid to cover the transpiration requirements of the plant. In the intact plant sufficient water is transmitted through the root system to cover the transpiration requirements. In the intact plant, therefore, water is supplied to the shoot at a rate which is in excess of the rate at which the root system unaided could supply it, as shown by the rate at which liquid exudes from the stump of a decapitated plant. Under these conditions the root system constitutes a resistance to the flow of water, a fact already pointed out by Kramer (1938).

Before going on to present estimates of the magnitude of the root resistance, an attempt will be made to show that the liquid which exudes from a cut stump is, in fact, derived from the cut ends of the xylem elements. Determinations have been made of the rate of exudation from intact stumps of *Bryophyllum pinnatum* and also from stumps, the outer tissues of which have been peeled back from the cut surface and the cambium carefully scraped off the exposed xylem surfaces. It was found that exudation took place at the same rate from both peeled and unpeeled stumps, provided that in the former all exposed surfaces of xylem, etc., were covered with a thin film of grease.

TABLE 3. Showing rate of exudation from intact and peeled stumps of *Bryophyllum pinnatum* in cc. per hour over a twenty-four-hour period.

	Intact	Peeled
	0.061	0.030
	0.033	0.047
	0.056	0.067
	0.060	0.053
	0.033	0.042
	0.057	0.050
Mean	0.050	0.048

Exudation from both peeled and intact stumps was still proceeding actively seven days after the experiment was set up. There is no doubt that here the exudate is derived from the central xylem core, though whether from the living or non-living elements of the xylem it is not possible to say. It is very doubtful, however, whether the few living cells of the xylem could exude liquid at the rates shown in table 2. This conclusion agrees with that of Kramer (1940) and lends no support to the views of James and Baker (1933). The assumption that the exudate is, in fact, derived from the cut ends of the vessels and tracheids of the xylem is an essential point in considering the data which will be presented later.

Experiments on root resistance.—Attempts have been made to get an estimate of the magnitude of root resistance in a number of species of plants and to assess its importance so far as the general water relations of the plant are concerned. The method adopted has been as follows. The rate of transpiration of an intact potted plant has been determined in the manner described earlier in this paper. The

TABLE 2.

Species	Transpiration gm./hour	Exudation gm./hour
<i>Strobilanthes</i> sp.	0.5 gm.	0.14 gm.
<i>Pelargonium</i> sp.	1.3 gm.	0.10 gm.
<i>Bryophyllum pinnatum</i>	0.10 gm.	0.02 gm.
<i>Impatiens noli-metangere</i>	0.28 gm.	0.19 gm.

transpiration rates of all the plants used could not be determined on the same day but all determinations were carried out as far as possible under uniform conditions. During the transpiration determinations the temperature was always within the limits 21°C. to 22.8°C. with relative humidity between 70 and 75 per cent, and the soil of the pots was well watered. All determinations were made in a greenhouse during periods of sunlight of moderate intensity. To avoid, as far as possible, errors due to transpiration taking place mainly at the expense of the water content of the leaf, the determinations were made over a four-hour period. In no experiment did any wilting of the leaf take place, and it has been assumed, therefore, that the observed transpiration rates represent the rate at which, in the intact plant, water was being supplied to the transpiring shoot. After completion of the transpiration determination, the plants were decapitated near the soil level and again well watered. A graduated pipette was then fitted to the stump, and recently boiled and cooled distilled water was introduced into the pipette. To avoid drying of the cut surface decapitation was done under a stream of water. A negative pressure was applied to the upper end of the pipette by means of a water pump, and the rate at which the level of the liquid in the pipette rose was determined. A negative pressure of 70 cm. of mercury was used. With an efficient water pump connected direct to the main this pressure could be maintained with no sensible fluctuations for several hours. Certain precautions had to be observed. All joints needed to be wired. As soon as the negative pressure was applied, an immediate small rise of the level of the liquid in the pipette occurred. This was due to contraction of the rubber tube used for making the joints, and the level of the liquid fell to its original value when the pressure was released. At the commencement of an experiment, air bubbles were often pulled out of the stump for a few seconds, and no accurate reading of the level of the liquid in the pipette could be made until this bubbling ceased, and this usually occurred after a few seconds had elapsed. Under these conditions liquid was sucked from the root system and continued to be delivered for some hours as shown by the data below for a plant of *Bryophyllum pinnatum*.

The rate of exudation falls off with time. This is almost certainly due to blocking of the cut surface, as the exudation rate is restored to its original value

TABLE 4. Exudation from a stump of *Bryophyllum pinnatum* under a negative pressure of 70 cm. of mercury.

Time	Amt. of exudation in cc.

if a fresh surface of the stump is cut. That the exudation is derived from the xylem is shown by the fact that exudation takes place at the same rate from peeled and intact stumps. The rate of exudation is affected by the magnitude of the pressure employed. At very low pressures the rate of exudation was so slow that accurate readings could not readily be made, but table 5 shows the rate of exudation for two pressures, namely 35 cm. and 70 cm. of mercury, from a stump of *Bryophyllum pinnatum*, a fresh surface being cut before the second determination. Pressures greater than 70 cm. of mercury could not be employed.

TABLE 5. Rate of exudation from a stump of *Bryophyllum pinnatum*.

Pressure cm. of mercury	Rate of exudation cc./hour
35	0.32
70	0.63

The rate of exudation is seen to increase as the pressure used increases.

The main results obtained are assembled in table 6. Altogether data for thirty-eight plants are given representing eighteen species. Column 2 shows the rate of transpiration in grams per hour for the intact plant and column 3 the rate of exudation from the stump of the same plant under a negative pressure of 70 cm. of mercury. The exudation rates are given in grams per hour. Since the exudation rate from a stump falls off in time, these determinations were carried out over a period shorter than one hour (usually fifteen minutes), and from this figure the rate per hour was calculated. By this means the effect of the falling off, which is believed to be due to blocking of the cut surface, is minimized. Column 4 shows the rate of exudation expressed as a percentage of the transpiration rate. When more than one plant of any species was used, the mean value for that species is incorporated in the table.

The absolute values for both the transpiration and exudation rates have, of course, little significance, since the values obtained will depend largely on the size of the plants. Actually all the plants used were fairly uniform in height (25 to 30 cm.) but they differed widely in the areas of transpiring foliage which they carried. Nevertheless fairly satisfactory agreement is shown between duplicates of the same species, especially when the exudation is expressed as a percentage of transpiration. Considerable variation is shown by the plants of *Bryophyllum pinnatum* but duplicates of other species agree well. The values found vary widely from species to species, from 7 per cent for *Hakea* and *Erica* to 77 per cent for *Pelargonium sanicifolium*.

The opportunity was taken to compare root and stem resistance for a few plants. To do this the rate at which water was transmitted through a 15 cm. length of stem was determined for a negative pressure of 70 cm. of mercury in the way previously

described, and this was compared with the exudation rate from the stump of the same plant when a negative pressure of 70 cm. was applied. The data so obtained are incorporated in table 7.

The data emphasize the unimportance of stem resistance in affecting the flow of water to the transpiring leaves and confirm the suggestion previously made in this paper and by Kramer (1938) that the

resistance offered by the stem to the upward flow of water is of relatively little importance.

Reference to the main table shows that only with a single plant of those tested did the rate at which liquid could be sucked from the root system equal the rate at which the intact plant lost water by transpiration. As pointed out previously the actual values for the exudation rate have little significance. The rate at which liquid is delivered from the stump is almost certainly affected, not only by the structure of the root but by the distance of the absorbing region of the root from the cut surface of the stump and by the extent of the absorbing surface. Since the plants used were all growing in pots, differences due to these factors were probably not so great as they would have been with plants with an unrestricted root range. The differences in transpiration rate observed reflect, not only any inherent differences in the rate of transpiration, but also differences in the area of transpiring foliage carried by the plants. The most interesting statistics are those of column 4 showing the exudation as a percentage of transpiration. Here there is a large variation between species. The succulents give fairly high values, especially the two species of *Bryophyllum*. The values for *Hydrangea hortensis* and the various species of *Pelargonium*, too, are fairly high, two species of *Pelargonium* giving values higher than the *Bryophyllum*. The lowest values are all given by the three xeromorphic plants, *Erica*, *Hakea* and *Acacia*. *Gomphocarpus* and *Quillaya* give somewhat higher values, while the other species (represented only by single observations) occupy an intermediate position. In general the succulents and mesophytes tend to give high values and the xerophytes low values. The values given, of course, refer only to the conditions of this particular experiment.

Discussion.—In the intact plants when transpiration is not taking place at the expense of the water content of the foliage, the root system is supplying water at the same rate that water is being lost from the shoots by transpiration. When a negative pressure of 70 cm. of mercury is applied to the stump of a decapitated plant the contents of the tracheae and of the stump will be subjected to a tension equivalent to 70 cm. of mercury. As the experiments which

have been described show, such a tension is not sufficient to cause water to be delivered from the root at a rate sufficient to cover the transpiration requirements of the plant. To ensure a supply of water sufficient for transpiration needs, the contents of the tracheae must be under a tension considerably in excess of 70 cm. of mercury. This suggestion makes it unnecessary to suppose that the passage of water from living cells of root to the tracheae is due to the osmotic pressure of the tracheal contents. It is not osmotic pressure but the suction force of the tracheal contents which is important. With a cut stump such as is usually employed for root pressure experiments, exudation is probably due mainly to the osmotically active substances present in solution in the tracheal contents. In the intact plant when transpiration is active the suction force may be due, in part, to the presence in the tracheae of a solution which exerts a considerable osmotic pressure, but it is probably due to a greater extent to the tension of the tracheal contents (Kramer, 1932). A conducting system which is surrounded by living cells with semi-permeable protoplasts will exert a suction force if its contents are in a state of tension, even if the liquid in the system does not contain osmotically active substances in solution. The existence of such a tension, therefore, will be sufficient in itself to cause a flow of water from the living cells of the root to the tracheae as long as the tension is greater than the suction force exerted by the surrounding living cells.

Evidence has been presented to show that the tension required to overcome the resistance of the root to water transmission varies considerably from species to species. While such tensions may be well below the tensions which expressed plant sap can transmit, there is the possibility that they at least approach the maximum pull which the transpiring leaves can exert, at the same time maintaining a condition of turgidity. If we accept the view of Atkins (1916) and look on the whole of the living cells of the root as constituting a semi-permeable membrane separating the soil solution from the xylem contents, then the suction force of the tracheal contents causes an inward flow of water from soil to xylem against the resistance offered by the living cells to water transport. The suction force necessary is, it is suggested, supplied largely by the tension of the tracheal contents. The resistance to water movement in the leaves is known to consist mainly of the resistance offered by the mesophyll cells (Mer, 1940). Even the finer veins offer little resistance to water movement. It is likely that, in the same way, the important resistance offered to water movement by the roots is that of the living root cells.

THE TENSIONS OF THE CONTENTS OF THE TRACHEAE AND THE OSMOTIC PRESSURE OF THE CELL SAP OF THE LEAVES.—It has been shown that the rate at which a decapitated stump of a plant exudes liquid, when subjected to a negative pressure of 70 cm. of mercury, rarely equals the rate of transpiration from the intact plant when conditions favor a relatively

high transpiration rate. It was concluded, therefore, that under these conditions the contents of the tracheae must be under a considerable tension. If we assume that the rate of exudation is proportional to the pressure employed, we can get an estimate of the tension which must have existed in the tracheae of the intact plant. This has been done and the values so obtained checked against direct observations on the relative tensions existing in the tracheae of the plants used. The values found by the two methods show a close correspondence.

Experimental.—Estimates of the tensions of the tracheal contents of intact plants were obtained by assuming that the rate of exudation from the stump was proportional to the magnitude of the negative pressure applied to the stump and from a knowledge that, over an extended period in the absence of wilting, transpiration is equal to the supply of water from the root.

This method of estimating the tensions may involve considerable errors, so that too much stress will not be laid on the absolute values given. The errors will apply to all the estimates made, so that any classification of the plants used based on differences between the estimated tensions in the tracheae is likely to be accurate.

Direct observations of the relative tensions in the tracheae were made using a method previously employed by Baker and James (1933). The method consists of fixing a small plasticine cup to the stem of the plant, filling the cup with dye solution (1 per cent acid fuchsin), rapidly piercing with a sharp knife the stem underneath the surface of the dye solution and determining the extent to which the dye immediately penetrates both upwards and downwards in the xylem. In these experiments the plasticine cups were fixed near soil level and so only the extent of the upward penetration could be determined. The extent of the dye penetration will give a

measure of the tension of the tracheal contents provided material of uniform size is used. The plants used in these experiments were chosen for their uniformity in height, all being about 30 cm. high. The determinations were carried out in a greenhouse with air temperature 23°C. and relative humidity 65 per cent, with sunlight of moderate intensity, and the plants were all well watered so that the conditions were similar to those which prevailed when the transpiration determinations on which the calculated tension values are based were made.

Determinations of the osmotic pressure of the sap expressed from the leaves of some of the plants used were made. The osmotic pressures were calculated from the freezing point of the sap expressed from leaves which had been killed by immersion in liquid air.

The results obtained are assembled in table 8. In column 2 are given the values for the calculated tensions. The values given are in atmospheres. Only mean values are given, the number of values on which the mean is based being shown in parentheses. Column 3 shows the penetration of dye in the xylem in cm. Mean values only are given, the number of observations on which the mean is based being shown as before. In the fourth column are the values for the osmotic pressure of the sap expressed from the leaves. For the sake of convenience the species here are listed in the order of magnitude of the calculated tensions.

Reference to table 8 shows that the two methods employed for obtaining estimates of the tensions of the tracheal contents have given results which agree well. In the succulents and mesophytes the tension tends to be low and in the more xerophytic species to be high. This of course refers only to the plants under the conditions of these experiments. It is easy to show that the tensions undergo marked variations with changes in external conditions. This is shown

by some measurements of dye penetration made on plants growing outdoors. As the observations were made on material which was very variable as regards age and size and under varying conditions of exposure all the data will not be presented. Measurements made in the afternoon of August 26th with the temperature 18°C ., relative humidity 75 per cent and the soil very wet showed considerable dye penetration in shoots of Gooseberry, White Currant, *Hydrangea hortensis*, *Cytisus scoparius*, *Rhododendron ponticum*, *Berberis aquifolium*, *Taxus baccata*, and *Sambucus nigrus*. Measurements made on the same species during the morning of August 28th following about fourteen hours of continuous heavy rain, with the wet and dry bulb thermometers both reading 11.7°C ., showed a dye penetration of 4 cm. in *Cytisus scoparius*. In all the other species it was less than 1 cm. and was probably nil; but, owing to the fact that the stem is pierced below the surface of the dye solution in the plasticine cup, penetrations of less than 1 cm. cannot be determined readily because of contamination of the outer surface of the stem by the dye. This evidence of variation in the tension of the tracheal contents suggests that this may prove a useful method of studying the water relations of plants in the field (Warne, 1941), especially since we have here evidence that the tensions undergo marked changes and, with many species, disappear completely when water supply is good and transpiration nil for long periods, the rate of disappearance varying from species to species and the tension persisting longer in some species (e.g. *Cytisus scoparius*) than in others.

The data for the osmotic pressure of the cell sap of the leaves shown in the table vary from plant to plant. In general the tendency to develop a considerable tension in the tracheae accompanies a high osmotic pressure of the sap. In every case the estimated value for the tension is less than the osmotic pressure of the sap expressed from the leaves.

Discussion.—It is now possible to discuss these results in so far as they affect the general water relations of the plant. The generally accepted view of the mechanism of transpiration (Stiles, 1936) is that evaporation of water is either through the cuticle or into the intercellular spaces of the mesophyll, and that water vapor diffuses out through the stomatal pore and a gradient of suction force is set up between the evaporating surface and the tracheae, with the result that there is a flow of water from the tracheae to the evaporating surface. There is no *a priori* reason why water should pass from the tracheae to the evaporating surface. It will do so only as long as a suction force gradient is maintained. The greater the suction force exerted by the tracheal contents the less readily will water flow to the evaporating surface and the more will the water at the evaporating surface be withdrawn into the intercellular spaces of the cell wall, thus greatly increasing the resistance to evaporation. According to this view we can look upon the whole of the living cells as constituting a semi-permeable membrane sepa-

rating the evaporating surface from the tracheae. We cannot, however, neglect the fate of the living cells. If the latter are to remain turgid, they must be kept supplied with water. They can only remain turgid as long as the maximum suction force exerted by the non-flaccid cells is not exceeded by the suction force of both evaporating surface and tracheal contents. If the suction force of the evaporating surface is greater than the suction force of the tracheal contents and both are greater than the suction force of the living cells, water may pass to the evaporating surface through the living cells without maintaining the latter in a condition of full turgidity. Since even in a wilted leaf water continues to be transpired from the evaporating surface, we can assume that the maximum suction force of the evaporating surface is greater than the suction force of the tracheal contents, and the suction force of the latter is considered to be due mainly to the tension under which the liquid in the tracheae exists. So to maintain the living cells of the leaf in a condition of turgidity, their suction force must be greater than the suction force of the liquid in the xylem vessels and tracheids. It is to be expected that the maximum suction force of the leaf will be closely related to the osmotic pressure of their cell sap. On drying, shrinkage of the cell may occur before a fully flaccid condition is attained, so that the maximum suction force attainable may be considerably in excess of the osmotic pressure; there is also the possibility of rapid changes in composition of the sap, resulting in an increased osmotic pressure. Nevertheless, it is probably safe to assume that the osmotic pressure of the cell sap is a fair measure of the relative maximum suction forces which the cells of different plants are able to exert. Reference to table 4 shows that in all cases examined the osmotic pressure of the cell sap of the leaves exceeded the estimated tension of the tracheal contents. This accords with the observation that during these experiments no wilting of the leaves was observed. The data give a clue to the significance of the high osmotic pressures often found for sap of xerophytic plants. It was formerly considered (Fitting, 1911) that a high osmotic pressure of the leaf cell sap in itself depressed transpiration, but both Renner (1915) and Wisser (1914) consider the depressing effect of high osmotic pressures to be negligible. According to the views given above it is the suction force of the tracheal contents, due mainly to their tension, which will exert a depressing effect on transpiration rate, the significance of the high osmotic pressure of the leaf cells being that it allows the development of a considerable degree of tension in the tracheal contents without causing a flow of water from the living leaf cells to the tracheae. At the same time the tension facilitates passage of water from the living cells of the root to the tracheae. As long as the suction force of the tracheal content exceeds the suction force of the soil water, absorption is facilitated. The significance of the tension is at least twofold. It overcomes root resistance and facilitates water absorption and at the same time

reduces transpiration, and, as long as the tension does not exceed the maximum suction force of the non-flaccid leaf cells, it can do this without causing wilting of the leaf. The tensions disappear during periods of good water supply and low transpiration, and so probably the existence of the tension can be taken to indicate the existence of some slight internal water deficit, which, however, is prevented from becoming serious by the action of the tension itself on absorption and transpiration. We have here a self-regulating mechanism for preventing the development of a serious internal water deficit, but the efficiency of the mechanism is limited by the level of the osmotic pressure of the leaf cells. It is precisely in those plants whose cell sap has a high osmotic pressure that there seems to be the greatest tendency for a considerable tension to develop during periods when conditions favor high transpiration, and this, in itself, is likely to postpone the time when a serious deficit of water in the leaves occurs.

SUMMARY

The water conductivities of the stems of a variety of plants have been determined, and it has been shown that the conductivity per unit area of foliage supplied varies according to the species, the lowest value being given by *Ruscus aculeatus*.

An estimate of the pressure needed to raise water to the cladodes of *Ruscus* at a rate sufficient to cover the transpiration losses gave a value so low as to indicate that, even in this extreme case, stem resistance is unlikely to offer a serious obstacle to the upward movement of water to the transpiring cladodes.

Liquid exuded from a cut stump is derived from the xylem, but the rate of exudation from the stump rarely equals the rate of transpiration from the whole plant. It is concluded, therefore, that, in the intact plant, water is transmitted through the root system at a rate in excess of the rate at which a cut stump exudes liquid. It is necessary, therefore, to look upon the root system as constituting a resistance to the flow of water from the soil to the transpiring shoot.

Measurements have been made of the rate at which the stump of a well watered potted plant exudes liquid when subjected to a negative pressure. This rate of exudation has been expressed as a per-

centage of the rate of transpiration from the same plant, and the exudation rate expressed in this way varies considerably from species to species, the highest values being obtained for succulents and mesophytes and the lowest for xerophytes. The exudation rates obtained in this way give a measure of root resistance. A high exudation rate indicates a low root resistance and *vice versa*.

It is concluded that, in the intact plant, root resistance is overcome by the suction force exerted by the solution in the xylem and that this suction force is contributed to largely by the tension of the tracheal contents.

Estimates of the tension of the tracheal contents of intact potted plants are given. These estimates are based on a knowledge of the rate of exudation of a decapitated stump, when subjected to a known negative pressure, and of the transpiration rates of intact plants.

Data relating to direct observation of the relative tensions of the tracheal contents of plants are presented and show satisfactory agreement with the estimates mentioned in the above paragraph.

Values for the osmotic pressure of the sap expressed from the leaves of some of the plants used are given.

The estimates of the tension in the tracheae vary from 1.21 atmospheres for *Pelargonium sanicifolium* to 13.12 atmospheres for *Erica*, President Felix Faure. In general, under conditions favoring rapid transpiration, high values for the tension are found for xerophytes and low values for mesophytes and succulents. The tensions are reduced or disappear when plants are exposed to conditions in which transpiration is nil and the water supply good.

The tendency to develop a high tension in the tracheae may be advantageous in that it facilitates water absorption and tends to restrict transpiration.

The significance of a high osmotic pressure of the leaf cell sap is that it allows the development of a high tension in the tracheae without the latter causing a flow of water from the living leaf cells to the veins. A high tension in the tracheal contents will assist in the maintenance of a favorable water balance as long as it is accompanied by a high osmotic pressure in the leaf cells.

AMERICAN JOURNAL OF BOTANY

Supplement to Volume 29, No. 10.....December, 1942

ABSTRACTS OF THE PAPERS PRESENTED BEFORE THE GENERAL, PALEOBOTANICAL, PHYSIOLOGICAL,
AND SYSTEMATIC SECTIONS OF THE BOTANICAL SOCIETY OF AMERICA

NEW YORK CITY

DECEMBER 29 TO 31, 1942¹

ANDERSON, LEWIS E., and HENRY I. KOHN, Duke University, Durham, N. C. *The effect of certain sulfa-drugs on root elongation.*—Young seedlings of peas, corn, and radish were grown by immersing primary roots in various concentrations of sulfanilamide, sulfathiazole, sulfapyridine, and sulfadiazene. Root elongation was measured after one to seven days. Both roots and solutions were analyzed for drug content and some roots were examined cytologically. Sulfanilamide and sulfathiazole inhibit root elongation to a degree somewhat proportionate to the drug concentration of the culture solution. Sulfanilamide is a relatively more potent inhibitor of root growth than sulfathiazole. Inhibition by both drugs can be abolished by the addition of *p*-amino benzoic acid to solutions containing the drug. The amount of *p*-amino benzoic acid required to abolish a fixed amount of inhibition depends upon the ratio between added inhibitor and added *p*-amino benzoic acid. Inhibition is brought about by a decrease in the rate of cell division. Low concentrations of both sulfanilamide and sulfathiazole stimulate root growth as do low concentrations of *p*-amino benzoic acid alone as well as when mixed with low concentrations of either drug. High concentrations of *p*-amino benzoic acid itself likewise inhibit root growth. Roots grown in saturated solutions of sulfapyridine and sulfadiazene are stimulated or not affected apparently because of the relative insolubilities of these drugs as compared with sulfanilamide and sulfathiazole.

AVERY, GEORGE S., JR., JULIUS BERGER, and BARBARA SHALUCHA, Connecticut College, New London, Conn. *Accumulation of auxin in maize kernels during ontogeny.*—Corn kernels were assayed for their auxin content at successive stages in their maturity. The extraction method used was that developed in 1940-41 for the rapid and total extraction of auxin and auxin precursor from corn endosperm. The precursor is an, as yet, unidentified compound which upon alkaline hydrolysis yields indoleacetic acid. The precursor always constitutes the major portion of the total auxin obtainable at any time. There is little or no auxin present at time of pollination, but accumulation begins immediately afterward, reaching its peak in about 3 weeks. At their peak auxin

content, kernels contain 30 to 50 million TDC per gram dry weight (equivalent to 0.3 to 0.5 mg. indoleacetic acid). There is a marked drop in auxin content as the kernels approach dormancy, characteristic of all varieties studied. No relationship is apparent between auxin which accumulates in kernels, and the vegetative vigor of the plants producing them (inbreds vs. hybrids); nor is there any evidence of a relationship between polyploidy and auxin content. Kernels with sugary endosperm are consistently higher in total auxin than those with starchy endosperm.

BAILEY, I. W., Biological Laboratories, Harvard University, Cambridge, Mass. *Morphology and relationships of the Winteraceae.*—The Winteraceae is a remarkably homogeneous family as regards the morphology of its flowers, pollen, nodal anatomy, and wood structure. It exhibits a combination of morphological characters that is indicative of relatively remote relationship to such ranalian families as the Magnoliaceae, Schizandraceae, and Trochodendraceae.

BALL, ERNEST, Carnegie Institution of Washington, Cold Spring Harbor, N. Y. *Growth in sterile culture of the shoot apices of Tropaeolum majus and of Lupinus albus.*—The shoot apices and subadjacent tissues of these plants have been grown in sterile culture for the purpose of gaining an understanding of the developmental potentialities of the embryonic and differentiating tissues. The shoot apex of *Tropaeolum* may grow in culture and produce a plantlet several centimeters long that consists of stem, leaves and adventitious roots. The shoot apex of *Lupinus* may produce a short shoot when grown in culture, but adventitious roots do not form under the conditions of the experiments. The young, differentiating tissues immediately behind the shoot apices of both *Tropaeolum* and *Lupinus* undergo a generalized growth in culture and produce a mass of tissue. The manner of growth of these tissues in culture indicates that the center of embryonic development in these plants is restricted to the shoot apex and does not extend to the subadjacent tissues. This is evidence of the physiological differences between the shoot apex and the tissues below it. Reorientations of these shoot apices with respect to the force of gravity did not change their polarity. In inverted or horizontal orientations, these shoot apices grew normally and produced short

¹ Because of a request from the Office of Defense Transportation, dated November 20, 1942, the meetings were not held on these dates but were postponed indefinitely.

shoots, the oldest ends of which then curved in a manner that tended to return the buds to the upright position.

BALL, ERNEST, and EDGAR J. BOELL, Carnegie Institution of Washington, Cold Spring Harbor, N. Y., and Yale University, New Haven, Conn. *Respiration of the shoot apices of Lupinus albus and Tropaeolum majus*.—The rates of oxygen consumption of the shoot apices and of subjacent, differentiating tissues of *Lupinus* and *Tropaeolum* have been measured with the Cartesian diver ultramicrorespirometer in order to obtain information on the relationship between metabolic rate, dominance and embryonic development. In *Lupinus*, a plant having apical dominance, a gradient in respiratory rate exists along the apico-basal axis. The relatively high respiratory rate of the shoot apex is apparently due to fundamental physiological dissimilarities between it and the differentiating subjacent tissues where lower rates of respiration prevail. In *Tropaeolum*, which lacks apical dominance except during early seedling stages, the respiratory rate of the shoot apex is lower than that of the immediately subjacent region, and there are pronounced decreases in respiratory rate in tissues farther down the shoot. There appears to be a correlation between the respiratory rates of parts of the axis of *Lupinus* and its anatomical gradients, but in the axis of *Tropaeolum* no such correlation exists. The respiratory rate of the shoot apparently has no correlation with its function as a center of embryonic development. It is not possible to state whether the high rate of respiration found in a dominant shoot apex is the cause or the result of dominance.

BANFIELD, WILLIAM G., and IRENE H. STUCKEY, Rhode Island Experiment Station, Kingston, R. I. *Extent of intercrossing among Agrostis species*.—Preliminary study shows correlation of chromosome number with morphological characters in *Agrostis* species. There is as yet no definite evidence whether *A. alba* and *A. tenuis* are distinct species or variants of the same species.

BARGHOORN, ELSON S., JR., Amherst College, Amherst, Mass. *The occurrence of marine cellulose-destroying fungi*.—A new series of marine fungi has been isolated during the course of investigations on the structural and chemical changes in the decomposition of submerged wood. The fungi are of very common and wide-spread occurrence along the North Atlantic coast. Pure cultures of 12 species have been obtained from wooden test blocks which had been continuously submerged for six to ten months in the sea. Several additional forms have been isolated from specimens of decaying piling and cordage collected in Massachusetts harbors. The organisms thus far determined belong to the *Pyrenomyces* and to several groups of the *Fungi Imperfecti*. In many cases the occurrence of abundant perithecia has facilitated the solution of taxonomic and cultural problems. Histological and microchemical examination of infected wood and cordage shows that the fungi bring about the enzymatic

hydrolysis of cellulose in the thick secondary walls of the fibers. Plant materials attacked by these organisms exhibit a marked deterioration involving loss of cellulose and concomitant reduction in tensile strength. The physiological activity of these fungi on a wide variety of substrata is now being determined.

BERGER, JULIUS, and GEORGE S. AVERY, JR., Connecticut College, New London, Conn. *Auxins and certain dehydrogenases of the Avena coleoptile*.—The ability of auxins to control certain phases of plant growth is well known, but their mechanism of action is still unknown. The object of the present study was to isolate dehydrogenases in cell-free extracts of the *Avena* coleoptile, auxin test object, and to investigate *in vitro* the effect of synthetic auxins on these enzymes. Considerable amounts of malic, ethyl alcohol, isocitric and *l*-glutamic acid dehydrogenases were found in the extracts. Fumarase and aconitases were also present. Succinic dehydrogenase was not found in the extracts, which suggests, with other findings, that the usual four-carbon dicarboxylic acid cycle is not operative in the *Avena* coleoptile. Naphthaleneacetamide and indoleacetic, naphthaleneacetic and indolebutyric acids had no accelerating effects on the activity of the malic acid dehydrogenase. The fumarase and alcohol dehydrogenase activities were likewise not increased by indoleacetic or naphthaleneacetic acids.

BERRY, WILLARD, Duke University, Durham, N. C. *Pleistocene plants from South Carolina*.—From Wilson's Landing, Santee River, South Carolina, a Pleistocene flora of some 55 species has been found. The specimens consist of extremely well preserved leaves and seeds. These remains accumulated in cool water swamps but indicate a climate about like that of today in the area. They are all species which grow in the region today.

BLOCH, ROBERT, Yale University, New Haven, Conn. *Cellular competence, differentiation and pattern in meristems of Monstera deliciosa*.—Leaves, petioles and air roots were used in studying differentiation and pattern in surface tissues during primary development and in formation of cork, absciss and wound tissues. Natural and induced meristems from which surface structures are regenerated are of the storied type; the character of the elements differentiated is dependent on the stage of development of the organ and to some extent on external conditions. In very young organs primary cell types may be completely redifferentiated (epidermal cells in leaves), while in old and less reactive parts cells may only divide and suberize; mostly, however, derivatives of the secondary ground parenchyma meristems differentiated in a uniform manner, resulting in a surface structure with a simple pattern, which consisted of thin-walled suberized cells toward the surface, thick-walled lignified sclerotic cells underneath, and thin-walled parenchyma cells in the innermost region. Evocation and character of this pattern appear associated with conditions near the outer surface, but could

also be induced toward necrotic surfaces and centers in inner regions of petiole and air root. The pattern is very common in plant tissues adjacent to external and internal surfaces. As part of the general pattern it is often differentiated in primary development, for example, as hypodermal pattern in air roots of *Philodendrons*, under certain conditions also in those of *Monstera deliciosa*. If regions thus differentiated were experimentally removed the pattern was reconstituted by secondary meristems from the ground parenchyma and structural regeneration ensued.

BOKE, NORMAN, Johns Hopkins University, Baltimore, Md. *Development of the leaf and areole in Opuntia cylindrica*.—The leaf in *O. cylindrica* is terete, pointed, and about 3 mm. long. In its initiation and early development it resembles a typical leaf. However, since it forms no marginal meristem, it produces no lamina and is thus equivalent to the axis of a laminate leaf. A constriction developed at the base produces early abscission. An axillary meristem appears early on the enlarged and persistent leaf base. This begins to produce spines, glochids, and trichomes while the leaf is still immature. These structures are formed asymmetrically about the meristem and with it constitute the areole, which may be regarded as a modified axillary bud. The differences between spines and glochids seem to be quantitative. Glochids, however, are produced on the adaxial side of the areole apex whereas the larger spines are not. Both structures arise from several cell layers, and both grow from a basal intercalary meristem; however, neither contains any vascular tissue, although vascular tissue differentiates to their bases. Every epidermal cell within the limits of the areole, excepting those on spines, on glochids, and on the areole apex, produces a uniseriate trichome. These trichomes therefore appear in dense masses completely surrounding all other structures. Only basal trichome cells undergo divisions. Although spines and glochids appear to be the much reduced equivalent of leaves, further comparative studies are needed to solve the problem of homologies.

BONNER, JAMES, California Institute of Technology, Pasadena, Calif. *Observations on riboflavin and pantothenic acid in tomato plants*.—Concentrations of riboflavin and pantothenic acid in tomato plants growing in sand culture were determined under various circumstances. For assay of the two vitamins use was made of the micro-biological methods using *Lactobacillus casei*. With both substances a concentration gradient from top to bottom of the plant appeared to obtain, and this gradient was similar to that earlier reported for thiamin. When stems or petioles of the tomato plant were girdled by steaming, pantothenic acid appeared to accumulate above a basal girdle whereas riboflavin showed no such accumulation. The rate of accumulation of pantothenic acid under these conditions was greater than that of riboflavin but smaller than that of thiamin.

BROWN, ALLAN H., University of Rochester, Rochester, N. Y. *The unique respiratory system of Micrococcus candidus cohn*.—The respiratory system of *Micrococcus* was investigated by the use of the inhibitors, CO, KCN, NaN₃, NH₂OH, and NaF. Young broth cultures were washed free of nutrient and suspended in phosphate buffer containing glucose. The effects of the poisons were determined by manometric measurements of oxygen consumption. 3.3×10^{-2} M. NaF had no inhibitory effect. Apparently the course of glucose desmolysis does not follow the conventional Meyerhof pathway. CO-O₂ mixture in the ratio 19/1 produced no effect either in the light or in the dark and 1×10^{-2} M. KCN inhibited only 21 per cent of the respiration. This is strong evidence that cytochrome oxidase is not functioning. Oxygen consumption was inhibited 70 per cent by 3.3×10^{-3} M. NH₂OH and over 95 per cent by all concentrations of NaN₃ down to and including 1×10^{-4} M. With many tissues cyanide and azide exert much the same effects; this is the only biological material which has been shown to have a respiratory mechanism which is especially azide sensitive yet essentially cyanide resistant. As such, the respiration of *M. candidus* must be considered unique.

BRUMFIELD, ROBERT T., Harvard University, Cambridge, Mass. *The number and arrangement of initial cells in root meristems of Crepis capillaris and Vicia faba*.—Certain types of chromosome rearrangements induced by X-rays are passed on through subsequent cell divisions to all the descendants of the affected cell. Since the same chromosome change is not likely to occur in two adjacent cells, such rearrangements offer a means of "tagging" a single cell and determining the kind and extent of tissues that it produces. Primary root meristems in germinating seed of *Crepis capillaris* and *Vicia faba* were subjected to X-radiation and then allowed to grow for three weeks. During this period the meristem was replaced by descendants of initial cells present at the time of raying. After the growth period the primary tips were studied cytologically. Study of chromosome morphology showed many of the roots to be chromosomal chimeras. Most of the chimeras were sectorial ones, the same aberrant karyotype being found in a wedge-shaped sector including root cap, epidermis, cortex, and central cylinder. In most of the chimeras the sectors having the aberrant karyotype amounted to about one third of the root, and in one case three sectors of about equal extent were present. These results suggest that the whole root develops from but few cells, probably three, at the extreme tip of the root. These are arranged in such a way that sectorial chimeras are frequently formed while periclinal ones occur rarely, if ever. Sectorial chimeras would not be expected if the root meristem consisted of "histogens" as described by Hanstein.

BURKHOLDER, PAUL R., Yale University, New Haven, Conn. *Vitamin deficiencies in yeasts*.—Growth-responses were determined for thirty-eight

kinds of yeast cultured in a chemically defined medium with varied supplements of vitamins and liver extract. Under the conditions of the experiments, fifteen kinds showed marked requirements for thiamine, none for riboflavin, twelve for pantothenic acid, six for nicotinic acid, thirty-six for biotin, five for inositol, and six for pyridoxine. Growth of all yeasts was augmented by addition of liver extract to the medium containing the seven vitamins. Some of these organisms may be useful in microbiological assays for vitamins. Growth of *Saccharomyces oviformis* in an enriched medium is proportional to the dosage of pyridoxine up to approximately 0.001 gamma per ml. of culture fluid. The requirement of this yeast for pyridoxine appears to be rather specific inasmuch as a number of pyridine compounds related to vitamin B₆ were found inactive.

BURR, H. S., Yale University, New Haven, Conn. (Introduced by E. W. Sinnott). *Potential differences and fruit form in cucurbits*.—Electrometric methods have been so successful in unraveling fundamental biological problems that it has seemed worthwhile to investigate the relationship between the relatively steady state standing potential and pattern of organization in living systems. Such a relationship has been described in the amphibian egg and has now been extended to the ovary of races of *Cucurbita Pepo*. Pot-grown plants of three of these were studied: (1) a race with elongate fruits, about three times as long as wide; (2) a race with essentially isodiametric fruits, and (3) a race with disk-shaped fruits, about twice as wide as long. Potential differences have been determined by continuous recording over periods of time varying from 15 minutes to many hours. Fruits varying from 10 mm. overall length to 70 or 80 mm. were included. In all three fruits, over-all lengthwise potential differences were determined and transverse potential differences through the greatest diameters. It was found that in the long type, the lengthwise potential difference was seven times the transverse. In the round type, it was twice the transverse, and in the flat type from one to one-half times. These ratios of potential difference are independent of size. Radial asymmetries were also reflected in the potential pattern. In all dimensions the potential gradient in millivolts per millimeter was, in round numbers, one millivolt per millimeter. This preliminary study suggests a significant relationship between the field forces in the fruit and the form which it ultimately assumes.

CARABIA, J. P., New York Botanical Garden, New York, N. Y. *Endemism in the flora of Cuba*.—Cuba is rich in endemic species, but this is true only for two regions, the Pinar del Rio in the west and Oriente in the east. The rest of the island has the common vegetation of the West Indies. The chief families of endemics are Rubiaceae, Euphorbiaceae, Bignoniaceae, and Compositae. In Pinar del Rio they grow on a very old calcareous soil; in Oriente the endemics are on the Sierra Madre and represented on two types of soil: (1) on igneous vegetable

mold, the vegetation being close to that of Hispaniola; (2) on limonite, where the vegetation is most peculiar and has no close affinities.

CHANEY, RALPH W., University of California, Berkeley, Cal. *The record of local diversity in the Bridge Creek flora*.—The Bridge Creek flora from the John Day Basin of Oregon represents a middle Tertiary forest in which the redwood was a dominant tree. Collections and specimen counts from several localities have yielded a total of more than thirty-two thousand leaves and fruits, of which *Sequoia langsdorfi* and other fossil species with living equivalents in coastal California make up nearly eighty per cent. The remainder have equivalents now occupying regions with summer rainfall, in eastern North America and eastern Asia. There is a marked variation in representation between localities, and at one locality the percentage of certain species may vary greatly within short distances horizontally and vertically. *Cercidiphyllum crenatum*, a characteristic member of the East Asian Element, is well represented only at one locality (Dugout Gulch), and even here it may be rare or absent at certain pits. Such irregular occurrence is consistent with the observed occurrence of its living equivalent, *C. japonicum*, in Asia. *Fagus pacifica*, *Castanea orientalis* and *Tilia oregona* of the East American Element also vary greatly in abundance, as is the case with their living equivalents in the mixed deciduous forests of Kentucky. Suggestive of topographic control is the predominance of *Sequoia langsdorfi* at the Twickenham locality, where it makes up seventy-eight per cent of the total, and appears to indicate an essentially pure stand on a valley flat. The abundance of the small-leaved, evergreen oak, *Quercus clarnensis*, at Crooked River, where redwood makes up only three per cent, suggests greater slope exposure, possibly on the leeward side of a climatic barrier. Such quantitative data provide a basis for a better understanding of the composition and environment of Tertiary forests.

CHEADLE, VERNON I., Rhode Island State College, Kingston, R. I. *The origin and certain trends of specialization of the vessel in the Monocotyledoneae*.—The metaxylem in all available parts of 320 species in 35 families were investigated. Characteristic tracheids have great length, are angular in outline, have inconstant width of walls in transverse section when the wall is thick, and have no or very slight development of an end wall. Vessels have originated from such tracheids. Those vessel members nearest to the tracheids in these characters have scalariform perforation plates with over fifty bars on very oblique end walls. Those vessel members which are least like tracheids have simple perforation plates on transversely placed end walls. Tracheids are the most primitive upright conducting cells in the xylem and vessel members with short length, simple plates on transverse end walls, oval to circular outlines in cross section, and constant width of cell walls at all degrees of thickness are the most specialized. Vessel members with scala-

riform plates are intermediate in specialization. Those with the largest number of bars are the most primitive, while those with the smallest number are the most highly specialized among such vessel members. In essential features, both the (1) origin and the (2) lines of specialization of the vessel in the primary xylem of the Monocotyledoneae parallel those of the vessel in the secondary xylem of the Dicotyledoneae. It seems clear that vessels have originated independently in these two groups of the Angiosperms.

CHENEY, RALPH HOLT, Long Island University and the Brooklyn Botanic Garden, Brooklyn, New York. *China tea substitutes in the New York area.*—More than twenty-five species which are hardy in the New York area may be utilized for the preparation of beverage tea. Taxonomically, they represent a wide diversity within the Angiospermae. Many of them are palatable and harmless in terms of human physiology. Others are stimulatory in effect. Some are definitely undesirable both in taste and in action. A few are palatably pleasant but surprisingly deleterious otherwise. War transportation has reduced drastically the United States importation of approximately 100,000,000 pounds of China tea annually. Collection and private growing of tea substitutes has increased rapidly during the current year. The availability of acceptable species in eastern nurseries and in their native habitats has been investigated. Products of a single species and taxonomically mixed tea substitutes can be purchased on the New York Market.

CHRYSLER, M. A., and W. G. MCINTYRE, Rutgers University, New Brunswick, N. J. *The morphological nature of the photosynthetic organs of certain bladderworts.*—*Orchyllium Endresii*, a terrestrial bladderwort from Costa Rica, is particularly favorable for study because it has fairly well developed vascular tissues. The underground stem and the inflorescence axis have essentially the same stelar structure, characterized by many scattered phloem groups. The leaf-like organ has a stele almost exactly like that of the inflorescence axis. The vascular elements of the "leaf" arise from the stele of the stem as a concentric structure, i.e., a stele. In the bract subtending each pedicel, however, are found 3–5 collateral bundles arising separately from the stele of the axis. It is inferred that the so-called leaf in *Orchyllium* is a cladode. It is probable that the same is true of the small blade-shaped organs of species of *Utricularia*.

CHURCH, GEORGE L., Brown University, Providence, R. I. *A cytological and morphological approach to the species problem in Glyceria.*—In an examination of the somatic chromosomes of the North American species of *Glyceria*, it is found that *G. pallida*, *G. neogaea*, *G. pauciflora*, and *G. erecta* are distinct in having a diploid complement of fourteen large chromosomes. Correlated features include acuminate lodicules, lanceolate, erose-tipped paleas and rippled walls of the epidermal cells. The above species stand apart from the rest of the genus

and have some floret details more in common with other genera with a basic number of seven, such as *Poa*, *Festuca*, *Puccinellia* and *Fluminea*. The other members of the section *Hydropoa* have small chromosomes in multiples of ten; truncate or spatulate lodicules; lanceolate or ovate, notched paleas; smooth walls in the epidermis and two rather than three stamens. The somatic complements of these species are: *G. striata* 20, *G. elata* 20, *G. canadensis* 60, *G. obtusa* 40, and *G. melicaria* 40. In an intermediate position in the section is *G. grandis* with 20 medium size chromosomes; lanceolate, erose-tipped paleas; truncate lodicules and only slightly rippled epidermal walls. The section *Euglyceria* has small chromosomes in multiples of ten, lodicules shortened to a somewhat thickened and more or less continuous ridge, and obovate, winged, bidentate paleas. Diploid species ($2n = 20$) include *G. borealis* and *G. Cookei*. Tetraploid species ($2n = 40$) include *G. septentrionalis*, *G. acutiflora*, *G. occidentalis* and *G. leptostachya*. A tetraploid form of *G. septentrionalis* is reported from Nova Scotia, thus extending the range of this species. *G. fluitans* is represented by a diploid form ($2n = 20$) in the upper Sacramento Valley, whereas the Pacific and Atlantic coastal forms are tetraploid.

CLAUSEN, ROBERT T., and CHARLES H. UHL, Cornell University, Ithaca, N. Y. *The taxonomy of the subgenus Gormanina of Sedum.*—The species of *Sedum* grouped in the subgenus *Gormanina* seem to represent a natural evolutionary series divisible into two sections, both restricted to the Pacific Mountain System of western North America. The section *Rosulata*, comprising two species, appears to be the primitive section. The section *Eugormanina*, comprising four species, exhibits various advanced characteristics. The chromosome number, with one exception, is $2n = 30$. The exception is *Sedum oregonense*, of which the only plants so far studied are hexaploid. *Sedum obtusatum*, *S. laxum*, and *S. spathulifolium* are each divisible into subspecies which exhibit geographical or ecological distinctness as well as the morphological differences which are the basis for their recognition. Although we recognize only six species, previous workers have described sixteen species for the same plants which we assign to this subgenus. Further, these species have been placed in three different relationship groups, even with one subspecies in one genus and another subspecies of the same species in another genus. Finally, Section *Oreganica*, recently described and included in subgenus *Gormanina*, should be removed from *Gormanina* on a basis of cytological evidence and gross morphology.

COMMONER, BARRY, and DANIEL MAZIA, Queens College, Flushing, N. Y., and University of Missouri, Columbia, Mo. *The mechanism of auxin action.*—The effect of indole-3-acetic acid and the four-carbon dicarboxylic acids on the rate of salt accumulation and water absorption by aerated potato tuber slices and *Avena* coleoptile sections was studied. Optimal concentrations of auxin produced a marked stimu-

lation of salt and water absorption. Both processes are a function of the auxin concentration, following the usual optimum curve closely parallel to each other. The optimum auxin concentration for both salt and water absorption by potato slices is 10–20 mgm. per liter; for *Avena*, 1 mgm. per liter. In hypertonic sucrose solutions auxin prevents the normal loss of water by potato slices, and in the presence of KCl causes water to be absorbed and the tissues to become turgid. This fact contradicts the wall extensibility theory of auxin action (proposed by Heyn *et al.*) since such slices do not have the initial turgor required by this theory. The presence of the four-carbon acids appears to be necessary for the auxin effect, thus confirming similar observations on the growth effects of auxin. It is concluded that the active driving force which causes cell enlargement is the accumulation of salt in the cell sap, since this process induces the absorption of water and increase in cell volume. Auxin influences cell enlargement through its effect on salt accumulation. The energy required by salt accumulation is probably derived from the metabolic activity of the four-carbon acid hydrogen transport system. Auxin appears to play an important part in this process.

COUCH, GLENN C., and ELROY L. RICE, University of Oklahoma, Norman, Okla. *Conjugation in a species of Desmidium*.—A collection of conjugating *Desmidium* was made in Southeastern Oklahoma (McCurtain Co.) in the fall of 1941. Although there is little doubt but that the species is *D. Grevillii* (Kutz) Debarry the type of conjugation exhibited by these specimens is quite different from that previously described. The conjugating cells in the filament do not dissociate, and the smooth walled spores develop in the receptive gametangia. Conjugating filaments over two hundred cells long were observed.

CROSS, GEORGE L., University of Oklahoma, Norman, Okla. *Further studies of the shoots of the Taxodiaceae—Athrotaxis and Taiwania*.—The cellular patterns in the shoot apices of *Athrotaxis* and *Taiwania* are similar to those of other genera of the Taxodiaceae. At the summit of each apex there is a single tier of apical initials which divide periclinally as well as anticlinally; lateral derivatives of the apical initials differentiate into a well defined protoderm; basal derivatives of the subapical initials become subapical mother cells; and derivatives of the subapical mother cells differentiate into a ring or cylinder of peripheral meristem and a core of pith mother cells. The apices of *Athrotaxis* are comparatively small (65–120 microns in diameter, measured in a plane equidistant from the shoot tip and the axil of the youngest leaf) and are hemispherical as seen in longisection. On the other hand, the apices of *Taiwania* are more massive (90–160 microns in diameter) and appear parabolic in longisection.

CROSS, GEORGE L., University of Oklahoma, Norman, Okla. *The shoot apices of the sequoias*.—The shoot apices of *Sequoia* and *Sequoiadendron* are similar to those of other genera of the Taxodia-

ceae. The apical meristem in each genus consists of a tier of apical initials, a flanking protoderm, a group of subapical initials, a peripheral meristem and a core of pith mother cells. This description is not in accord with those of Strasburger (1872) and Douliot (1870) for *Sequoia sempervirens*. The apical meristem of *Sequoia* is greater in diameter than that of *Sequoiadendron*. This difference in size is a result partially of differences in cellular number; however, statistical analyses show that the nuclear diameters, minor dimensions and major dimensions of the subapical mother cells of *Sequoia* are from twenty to thirty per cent greater than those of *Sequoiadendron*, and it is clear from this that differences in cellular size are involved also. The nuclei and cells of *Sequoia* exhibit greater variations in size than do those of *Sequoiadendron*. It is assumed that the differences in the shoot apices of the two genera are a result of polyploidy in *Sequoia*, and it is suggested that the determination of nuclear size, from "smears" or other preparations, may prove to be useful as a preliminary method of separating diploid and polyploid individuals.

CURTIS, OTIS F., and PALMER J. WASLIEN, Cornell University, Ithaca, N. Y. *Diurnal changes in food content of hay and other crops*.—Cutting alfalfa late in the afternoon has given a product containing 10 to 24 per cent more actual dry matter per unit area of field and 78 to 140 per cent more total starch and sugar than is found in matched areas cut early in the morning. When expressed as percentage of fresh weight the gain during the day or loss during the night is likely to be still greater than when expressed on an absolute basis. The original content and the amount of gain is influenced by the weather conditions preceding as well as during the experimental period. The data clearly indicate that the time of day that forage crops are cut may have a significant effect on their food value.

DALE, E. E., Union College, Schenectady, N. Y. *Dominance effects on floral pattern in a multiple-allelic series in Salpiglossis*.—The five normal or primary corolla lobes in *Salpiglossis* flowers usually maintain their identity in extra-lobed flowers and thus the location of the extra lobes can be determined. By designating the major corolla lobe 1 and the rest clockwise 2, 3, 4 and 5 an inbred strain of "extra-lobed" showed that 66 per cent of the flowers bore an extra lobe both in region 1–2 and 5–1. In 20 per cent, extra-lobing occurred at only one point, 9.6 per cent in region 1–2 and 10.4 per cent in 5–1. The remainder were chiefly multiple extra-lobed flowers in which the location of some of the extra lobes was uncertain. Thus the chances were 86 per cent that an extra-lobed flower would have its extra lobe or lobes immediately adjacent to lobe 1. In crosses, "extra-lobed" x "normal" gave 1.7 per cent of "extra-lobed" to 98.3 per cent normal flowers in F_1 , "extra-lobed" x "notched" 2.9 per cent "extra-lobed" to 97.1 per cent "normal," and "extra-lobed" x "cut" 85.6 per cent "extra-lobed" to 14.4 per cent "normal." "Extra-lobed," therefore,

was dominant only to "cut." A different result was obtained in the cross "extra-lobed" x "appendaged." Here the F_1 progeny showed 1.3 per cent of extra-lobed flowers, 14 per cent "normal" and 84.7 per cent in which one or both halves of lobe 1 were "notched." As far as observed, the remaining lobes (2-5) of the notched-lobe 1 flowers were "normal." Thus "extra-lobed" tends to produce a specific modification of the corolla pattern and gives three distinct types of effect in crosses with other members of the multiple series.

DIMOND, ALBERT E., and JAMES G. HORSFALL, University of Nebraska, Lincoln, Nebr., and Connecticut Agricultural Experiment Station, New Haven, Conn. *Chemical synergism*.—When a new compound is formed in a chemical reaction, its toxicity will usually differ from that of the original components. This fact led to the hypothesis that synergism and antagonism often result from chemical reaction of the components with each other. The hypothesis was tested by allowing two compounds to react, and assaying them and the product, chemically and biologically. Synergism and antagonism were proportional to concentration of the new product. A fungicidal system displaying synergism is CS_2 and dimethyl amine, yielding dithiocarbamic acid; one displaying antagonisms is ZnO plus mercaptobenzothiazole, yielding the zinc salt. In general, chemical synergism may result from (1) direct reaction, (2) reaction catalyzed by the living organism, or (3) reaction of one component (a) with a component (x) to form a product (ax) that is reactive with the second component (b). In each case the reaction product is the agent which determines toxicity. Conclusions: (1) In synergism, new compound formation may occur. If so, efficiency of synthesis of the active material can probably be improved. (2) Chemical synergism involving three components will be rare as compared with synergism involving two components.

DODD, JOHN D., Columbia University, New York, N. Y. *Three dimensional cell shape in the carpel vesicles of Citrus grandis*.—Internal cells from the carpel vesicles (juice sacs) of grapefruit were examined in the living condition. Cell walls were stained lightly with neutral red. Records were kept by making a careful drawing of each cell. In order to insure completely impartial selection the data were not tabulated and summarized until 100 cells had been drawn. Results showed an average of 13.85 faces per cell. The range in number of faces was from 9 to 18. The largest number of any one type was 22 cells each with 14 faces. Of the rest 39 cells had more than 14 faces and 39 had less. The number of edges per face varied from 3 to 8; 0.8 per cent were triangular; 25.9 per cent were quadrilateral; 41.6 per cent were pentagonal; 23.6 per cent were hexagonal; 7.0 per cent were heptagonal; and 1.1 per cent were octagonal.

DORF, ERLING, Princeton University, Princeton, N. J. *Late cretaceous-early tertiary floral changes in the Rocky Mountain region*.—A study

of the fossil record indicates (1) that from early Late Cretaceous to the end of Late Cretaceous time floral changes in the extensive lowland plains of the present Rocky Mountain region took place at a slow, uniform rate; (2) that at the end of the Late Cretaceous relatively rapid and far-reaching changes occurred, eliminating many of the "ancient" subtropical Cretaceous species, genera, and perhaps even families; even more marked changes occurred in the animal kingdom at this same time, including the extinction of the dinosaurs and the ammonites; (3) that the more modern, temperate vegetation of the early Tertiary (Paleocene) was quickly established over wide areas. An explanation of this rapid floral change is sought in one or another, or combination, of the following theories: widespread unrecognizable hiatus between rocks of Late Cretaceous and early Tertiary age; insufficient collections from critical beds; the effects of diastrophism on the vegetation; drifting of continents; sudden invasion; geographic changes in lands and seas; and changes in solar radiation.

EIGST, O. J., University of Oklahoma, Norman, Okla. *A comparative study of mitosis in diploid and tetraploid species*.—A comparison of the rate of mitosis in cells of diploid and tetraploid species was made through a study of the division of the generative cell of *Polygonatum biflorum* (diploid $2n = 20$) and *P. canaliculatum* (tetraploid, $2n = 40$). Three replicates of pollen cultures were kept in a germinating chamber for four, five, and six hours, respectively, and then fixed and analyzed for mitotic activity. Diploid and tetraploid pollen samples were planted on the same slide in separate locations; hence the comparisons of mitotic rate were made upon the two cytological types developing under the same conditions, for any given replication. Percentages of pre-metaphases and post-metaphases of the generative cell were used to calculate rates of mitosis. At four hours, mitosis was already underway in the diploid cells; however, the tetraploid did not show indications of division. There were greater numbers of post-metaphasic stages in four, five, and six hour replications among diploid, than tetraploid. The accelerated rate of mitosis is correlated with earlier flowering and more rapid maturation in the diploid as compared with the tetraploid. This method for determining mitotic activity of diploid and tetraploid cells offers opportunity for further comparative work with diploid and tetraploid material.

ELIAS, MAXIM K., University of Nebraska, Lincoln, Nebr. *Structure of grass and its evolution*.—The fundamental feature in the organization of grass stems is the arrangement of their vascular skeleton into nodes and internodes in such a manner that at each node a radially symmetrical circle of vascular bundles enters the leaf sheath. In ontogenetically early types of stems there is a single ring of vascular bundles in the internode. The closed, radially symmetrical sheath is apparently primitive and the more common split type is prob-

ably derived from it. Although the leaf of grasses differs greatly from that of *Equisetum* their basal parts are essentially similar and may be considered compound vegetative organs which are made of webbed small single-veined elementary leaves. If the two plant types did not originate from a common ancestral stock this similarity presents a striking case of homoplasticity. In the flowering glume or lemma of the late Tertiary Stipeae all parts find their homologues in the corresponding parts of the typical vegetative leaf of living grasses. But some of these parts are reduced and even suppressed in various representatives of living Stipeae. Because both lemma and vegetative leaf in modern grasses are adapted correspondingly to functions of flower protection and seed-dispersal, and of assimilation, their differences apparently increased with increase of adaptation. The leaf of the ancestral grasses may be expected to be less specialized.

EYSTER, H. C., University of South Dakota, Vermillion, S. D. *Adsorption: the mechanism of enzymes, sulfanilamide, antagonism, vitamin c, and selenium poisoning*.—Just as the adsorptive capacity of finely ground activated charcoal for methylene blue is decreased by ethyl alcohol, ether, chloroform, sodium barbital, sulfanilamide, and saponin, so it appears that the activity of enzymes is reduced similarly by the same narcotics. The study involved the action of diastase on soluble starch at 25°C. It is concluded that enzymes do not act in a manner that can be explained by the law of mass action, since it was found that 1 M cane sugar reduced the action of diastase on soluble starch just as much as 1 M glucose did, and 1 M KNO₃ reduced the activity about twice as much. Sulfanilamide reduces the adsorptive capacity of charcoal markedly and only mildly affects enzyme action. Hence, it appears that sulfanilamide acts bacteriostatically by reducing cellular and colloidal adsorption, possibly for food, while at the same time only slightly influencing the metabolism of the host. *p*-amino benzoic acid, although toxic in that it reduces cellular and colloidal adsorption, nullifies the bacteriostatic effect of sulfanilamide by *antagonism*. Data are available to show that the Cu-Ca, Ca, Na, and *p*-amino benzoic acid-sulfanilamide-antagonisms are partial or complete cancellations of each other's toxicity in decreasing adsorption when acting alone or in an unbalanced mixture. Vitamin C (50 ppm) was found to increase by 23 per cent the adsorptive capacity of charcoal for methylene blue at 25°C. The reaction is not due to the reducing capacity of vitamin C. Selenium (100 ppm) as sodium selenite was found to reduce adsorption of charcoal 35 per cent, and to be successfully antagonized by arsenic as sodium arsenite.

FERNALD, M. L., Gray Herbarium, Cambridge, Mass. *An amateur detective in a grassfield*.—Study of type of *Erianthus brevibarbis* Michaux shows it to be not the coastal plain species usually so called, but a rare plant of the Mississippi Basin.

FERNALD, M. L., Gray Herbarium, Cambridge, Mass. *An amateur detective in the carrot patch*.—*Angelica triquinata* described by Michaux from "Canada" proves to be the Alleghenian *A. Curtisii* Buckley, the supposed region "Canada" being a misprint for "Carolina."

FLINT, LEWIS H., Louisiana State University, Baton Rouge, La. *The reappearance of a large oscillator in Louisiana*.—In 1938 a large *Oscillatoria* was found at several places in Louisiana, the material being the subject of a brief report to this Section at the Richmond, Va., meeting of that year. During subsequent years unsuccessful attempts were made to find the plant. During the past summer the *Oscillatoria* of the 1938 collections was found to be plentiful at one of the original sites. This reappearance suggested that the plant might be of the interesting type or group designated as ephemeral. Some of the distinctive characteristics are restated.

FLINT, LEWIS H., Louisiana State University, Baton Rouge, La. *Note on photosynthetic activity in seeds of the spider lily*.—Experiments conducted with seeds of the spider lily afforded evidence that the reserves supplied to the ovule following fertilization were utilized in the development of accessory structures, including chlorophyllous tissue. The mature seeds did not take up water upon immersion, nor germinate while immersed, yet when such conditions permitted photosynthesis there was an appreciable accumulation of starch in the embryo. It appeared that both the development of the embryo and the germination of the seed were made possible largely through the photosynthetic activity of the chlorophyllous tissue developed from the integuments.

FRENCH, C. S., ELOISE NEWCOMB, and M. L. ANSON, University of Minnesota, Minneapolis, Minn., University of Chicago, Chicago, Ill., and Rockefeller Institute, Princeton, N. J. *The evolution of oxygen from illuminated suspensions of chloroplasts*.—Further experiments on the O₂ evolution (the Hill reaction) by illuminated spinach chloroplasts suspended in sucrose solution containing ferric iron, oxalate iron and ferricyanide iron have shown that there is a pH change due to the binding of a basic constituent or to the production of an acid which is not carbon dioxide. The phosphate previously used as a buffer can be omitted thus allowing a greater range of iron and oxalate concentrations to be used without tying up the iron as a phosphate complex. In phosphate-free solution we have found that up to about 0.5 M the O₂ evolution increases with an increase in oxalate, but at higher concentrations the rate becomes independent of the oxalate concentration. The ferricyanide which is essential to prevent the accumulation of ferrous iron during the reaction is itself also an inhibitor. There is, therefore, an optimum concentration of this substance at about 0.015 M, above or below which the rate of the reaction decreases.

GAISER, L. O., McMaster University, Hamilton, Ontario, Canada. *Pollen mother cell division*

in *Martynia louisiana* Mill.—Following the first nuclear division of meiosis no cell plate is formed and the spindle fibers disappear. A dense perinuclear zone of lipoidal content that alternately surrounds the nucleus and achromatic figure (perispindle zone) becomes divided and surrounds each daughter nucleus. After second division no fibers persist and areas of lighter staining, presumably more fluid cytoplasm separate the four daughter nuclei. Centripetal furrows, which are believed to be invaginations of the plasma membrane, advance through these while callose material, such as secreted about the mother cell protoplast is also secreted in the furrows as cytokinesis progresses. Thus the mechanics of furrowing is accomplished independent of any fibers.

GALSTON, ARTHUR W., University of Illinois, Urbana, Ill. *The extraction and analysis of intact oat chloroplasts*.—Intact chloroplasts were isolated from oat leaves by a technique previously described by Granick. Microkjeldahl analyses of entire leaf and chloroplast fractions indicated that at all stages of growth, in both green and chlorotic leaves, the chloroplasts contain 30–40 per cent of the total leaf nitrogen. Since about 80 per cent of chloroplast nitrogen is protein nitrogen, the chloroplasts must synthesize large amounts of the protein of the leaf. Chloroplasts transferred to hypotonic solutions gradually swelled and burst, indicating the presence of a semipermeable membrane around each plastid. Complete precipitation of plastids from an aqueous suspension was obtained by the use of a heat-labile agglutinin extracted from castor bean seeds. The apparent isoelectric point of the agglutinin was 4.6, indicating that it might be the albumin ricin, which also possesses erythrocyte-agglutinating properties.

GIER, L. J., William Jewell College, Liberty, Mo. *Root systems of Burley tobacco*.—A preliminary study of the roots of the Burley tobacco in loess soils shows fewer but more widely distributed roots than reported for Bright Belt tobacco.

GILLY, CHARLES L., New York Botanical Garden, New York, N. Y. *The phylogenetic development of the inflorescence in Carex and related genera*.—Three sorts of developmental trends have been operative in the production of the diverse inflorescence types of the tribe Cariceae. On the basis of a combination of inflorescence morphology with geographical distribution, a phylogenetic series is postulated. The significance of the floral structure in the group is considered, and the relationship of *Carex* and associated genera to the remainder of the family Cyperaceae is discussed.

GILLY, CHARLES L., New York Botanical Garden, New York, N. Y. *Floral structure and classification in the subfamily Mimusoideae (Sapotaceae)*.—Study of western hemisphere Sapotaceae has revealed that terminology of floral parts in the subfamily Mimusoideae (Hartog) Lam. seems to need reinterpretation. Correlative studies of eastern hemisphere members of the subfamily have been

necessary to further indicate the apparent evolutionary trends in the group. A partial result of this study has been the amplification of the subfamily to include certain genera previously placed in subfamilies Sideroxyloideae (Dubard) Lam. and Madhucoideae Lam. The relationship of the subfamily Mimusoideae, as herein constituted, to the remainder of the family is briefly discussed.

GLEASON, H. A., New York Botanical Garden, New York, N. Y. *Plant life of the Pacaraima range*.—The Pacaraima Mountains have long been noted for their numerous endemic species. The relationship of these endemics indicates that the flora has been derived partly from Andean and Amazonian sources, probably in comparatively recent time, but also contains plants showing distinct affinities with species of southern Brazil and West Africa. These facts contribute to new ideas on the origin and migrations of the American flora in general.

GORDON, ROBERT B., State Teachers College, West Chester, Pa. *Part of Rafinesque's herbarium discovered at West Chester, Pa.*—Examination of the century-old Darlington Herbarium in the possession of the State Teachers College at West Chester has brought to light more than 50 authenticated specimens from Rafinesque's collection. Historical records show that they were part of a collection of more than 1000 plants received by Dr. William Darlington from Elias DuRand, of Paris, in 1842. More than 20 specimens bear the original labels of the AUTIKON BOTANIKON and are among the few remaining illustrations of one of the rarest botanical works.

GRAHAM, E. R., and WM. A. ALBRECHT, University of Missouri, Columbia, Mo. *Nitrate adsorption by plants as an anion exchange phenomenon*.—Because of the importance given to the cation exchange from the clay of the soil to the root of the plant in what has been known as contact exchange and what has been demonstrated by means of calcium and hydrogen ion systems, the question naturally arises whether there cannot be anion change from the colloid to the plant in a similar manner. Experiments were carried out to determine the exchange capacity of a commercial product known as Amberlite. This colloid adsorbed the anion nitrates very readily. The exchange capacity of Amberlite used amounted to 160 M E of nitrate per 100 gms. of Amberlite in its moist condition, and to 319 M E when the Amberlite was dried at 100°C. This Amberlite was used as a carrier of the adsorbed nitrate. It was mixed into a subsoil that is very low in nitrogen and was used to grow corn plants. Potassium phosphate, 10 M E per three gallon jar of substrate, was used as a basic soil treatment in all trials. Three trials were completed. In the first were included the modified substrate, the substrate plus 15 gms. of Amberlite carrying adsorbed carbonate anion, and another treatment in which the Amberlite carried adsorbed nitrate ion. A second trial included two different amounts of calcium nitrate in solution and corre-

sponding amounts of the nitrate ion in the adsorbed condition. In the third trial nitrate was employed in solution and in the adsorbed form; both were subjected to a leaching treatment after the corn had grown for three weeks. The final crop was harvested at the end of six weeks. In the first case the Amberlite carrying the carbonate ion was without effect while the Amberlite carrying the adsorbed nitrate gave an effect almost exactly twenty times as large as that obtained on the Amberlite substrates without adsorbed nitrogen. When the crop growing on the Amberlite with nitrate was compared with a crop growing on the nitrate in solution, the results show that the adsorbed nitrate was as effective as the nitrate in solution. When the soils were leached, the leaching performance reduced the growth because of nitrate removal where it was applied in solution, but leaching was without effect as a reducer of crop growth where the nitrate was in the adsorbed condition. These results show that the nitrate ions in the adsorbed form are available for plant nutrition, and may be as effective as the water soluble nitrogen. Such results suggest that attention for purposes of plant nutrition may well go to the adsorbed anion as well as to the adsorbed cation.

GRAHAM, E. R., and WM. A. ALBRECHT, University of Missouri, Columbia, Mo. *Soil development and plant nutrition. II. Mineralogical and chemical composition of sand and silt separates in relation to the growth and chemical composition in soybeans.*—The recent demonstration that sands and silts, isolated from soils representing different climatic conditions, when treated with hydrogen clay, would effect the growth of soybean plants suggested that it would be worth while to characterize the chemical and mineralogical nature of these sands and silts as well as to determine the chemical composition of the plants grown. A rather complete analysis has been made. Methods for carrying out this type of analysis have been studied and developed. As a result of the various determinations it can be demonstrated that silts and sand containing the heavy feldspar fraction (Ca bearing feldspars) and a large suite of different minerals, will furnish nutrient cations for soybean plant growth, which result in soybeans of a high calcium and magnesium content. Also, the soybeans grown on the mineral-rich substrate fixed large amounts of nitrogen. Sand and silts containing quartz and potassium feldspars with a limited variety of minerals furnish few, if any, cations for soybean growth. The soybeans grown on the substrates poor in minerals fixed no nitrogen and contained very limited amounts of calcium and magnesium.

GREGORY, MARGARET P., The Blandy Experimental Farm, University of Virginia, Charlottesville, Va. (Introduced by O. E. White). *Chromosome investigations in the Aristolochiaceae.*—Approximately 15 species of *Asarum* native to North America and 30 species of *Aristolochia* from Europe and North, South, and Central America have been studied cytologically. In the South and Central

American group only diploid species ($n = 7$) of *Aristolochia* have been found while in the North American species only tetraploids ($n = 14$) have been observed. Both diploid and tetraploid chromosome counts have been made in European species. *Asarum* differs from *Aristolochia* not only in chromosome number ($n = 13$) but also in chromosome morphology. Correlation between chromosome complement and systematic grouping is noted. Possible association of polyploidy with other features is considered.

GUNCKEL, JAMES E., Harvard University, Cambridge, Mass. *Certain dynamic aspects of shoot growth in Ginkgo.*—Ginkgo affords an excellent illustration of short shoot—long shoot relationships, in which either shoot expression is capable of change to the other. Such changes may occur normally, or may be induced artificially. Experimental evidence, considered in the light of available information, shows: (1) that decapitation of the apical portion of any terminal or lateral branch results in the change to long shoots of a limited number of adjacent short shoots; (2) that application of auxin in place of the decapitated apical portion will effectively inhibit the short shoots below. It seems, therefore, that variations in short shoot growth are directly referable to variations in the rate of auxin supply. The growth control of apical buds, whether as long or short shoots, is very complex. Several possible explanations are suggested: (1) Apical bud expression may be dependent upon secondary inhibition from adjacent lateral branches. (2) Short shoots may have an increased rate of destruction of the auxin formed. (3) A deficiency, e.g., of nitrogen, associated with reduced auxin and also reduced vegetative growth, may be limiting in short shoot growth. (4) Prolonged cold treatment, possibly with excessive dryness, releases short shoots from apical inhibition.

GUNDERSEN, ALFRED, Brooklyn Botanic Garden, Brooklyn, N. Y. *The relationships of the Hamamelidaceae.*—The structure of flowers and of flower buds of *Liquidambar* and other genera of Hamamelidaceae is compared with similar structures of Hydrangeaceae, Platanaceae, Betulaceae and Cornaceae. The resemblances are of interest in connection with early fossil representation in these groups. A diagram presents carpel and stamen structure of various families of dicotyledons.

HITCHCOCK, A. E., and P. W. ZIMMERMAN, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y. *Modified organs and absence of correlative inhibition induced by p-chlorophenoxyacetic acid in Kalanchoe daigremontiana.*—In plants treated around the stem with lanolin preparations of p-chlorophenoxyacetic acid (3.2 — 10 mg./g.) correlative inhibition was lacking with respect to axillary shoot growth and to the growth of plantlets. Leaves were greatly modified as to size, shape, marginal serrations, and character of both surfaces. At the fourth or fifth node above the treated region most stems terminated in a funnel-

shaped organ 10 to 30 cm. long, variously cleft, with part or all of the margin smooth, and lacking a midrib although the tissue resembled that of leaves. Similar organs also developed in the axils of leaves or as modified leaves, sometimes resembling Jack-in-the-pulpit flowers in shape. From or near the margin of a terminal funnel-shaped organ 13 plantlets continued to grow, and now at a length of 6 to 9 cm. and with leaves 6 to 8 cm. long (with full complement of secondary plantlets), the shoots appear normal except for size. On control plants the plantlets seldom reached a length of 1 cm. In addition to the modified organs, four to six axillary shoots continued an indeterminate growth typical of normal stems. Of the several phenoxy and benzoic compounds tested, only *p*-chlorophenoxyacetic acid caused consistently and to the same degree all of the responses described.

HITCHCOCK, A. E., and P. W. ZIMMERMAN, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y. *Structure of phenoxy compounds in relation to root-inducing activity*.—The root-inducing activity of phenoxy compounds varied with the kind, number, and positions of substituents in the ring and with the relative length of the side chain. Compared with β -indolebutyric and α -naphthaleneacetic acids the root-inducing activity on cuttings of horticultural varieties was as follows for the substituted phenoxy compounds: the monohalogen substituted phenoxy acids were less, 2,4-dichloro- and dibromo-phenoxyacetic acids equal or greater, and the corresponding 2,4-propionic and butyric homologs and 2,4,5-trichlorophenoxyacetic acid 10 to 100 times greater. The activity for monosubstituted phenoxyacetic acids was: (*Euonymus*) para > ortho > meta; Cl > I at the ortho position; Cl > NH₂ > NO₂ at the meta position; and Cl > Br > NH₂ at the para position; (*Ligustrum ovalifolium*) m-NO₂ > p-NH₂ > p-Br, p-Cl, m-NH₂, m-Cl, o-Cl (latter five inactive up to 32 mg./l.). For other phenoxy acids (*Ligustrum*) 2,4-dichlorophenoxypropionic > 2,4-dichlorophenoxybutyric > 2,4-dichlorophenoxyacetic; phenoxybutyric acid > phenoxypropionic acid > phenoxyacetic acid; and for chlorophenoxyacetic acids (or ethyl esters) 2,4,5-trichloro- > 2,3,4,6-tetrachloro- > 2,3,4,5,6-pentachloro- > 2,4-dichloro- > monochloro- (o, m, or p). Mixtures of three dichlorophenoxy homologs or of one dichlorophenoxy homolog and either or both β -indolebutyric and α -naphthaleneacetic acids were more effective than the individual compounds. Phenoxy compounds induced marked fasciation of roots at concentrations near and above optimum. Phenoxypropionic and phenoxybutyric acids stimulated basal callus growth on *Ligustrum* cuttings, but induced relatively few roots. The alpha forms of propionic and butyric phenoxy acids were used in all cases.

HODGE, W. H., Massachusetts State College, Amherst, Mass. *Some aspects of the vegetation of Dominica, B.W.I.*—Because of its rugged terrain, which has restricted agriculture, the natural flora

of Dominica has been well preserved. This is not true of the majority of the Lesser Antilles which are heavily cultivated. A study of the vegetation of Dominica can thus serve as an example of the type of vegetation which formerly occupied most of the volcanic Caribbees. Four principal types of vegetation are recognized: (1) the pantropical vegetation of the strand; (2) the xerophytic scrub forest of the leeward coasts—typical of elevations up to 1000 feet; (3) the broad-leaved, evergreen, montane rain forest occurring between the 1500 and 2500 foot elevations; and (4) the mossy elfin forest of the highest summits—above 3000 feet.

HOPKINS, MILTON, University of Oklahoma, Norman, Okla. *A taxonomic study of Polygonatum in eastern and central North America*.—A recent paper by O. J. Eigsti involving cytological studies on *Polygonatum*, made by the colchicine pollen-tube technique, indicates that speciation within the genus is obviously due, at least in considerable part, to polyploidy. Continued work this year has further confirmed this conclusion. The present systematic treatment shows that the glabrous *P. biflorum* (n = 10) is restricted to the old Appalachian area of North America and that *P. canaliculatum* (n = 20), also a glabrous plant, doubtless is a polyploid, closely related to *P. biflorum*, and which occurs to the north and west in great abundance. It also occurs frequently within the range of *P. biflorum*. The specific differences between these two entities are indicated chiefly by *gigas* characters which are quantitative rather than qualitative. Even in herbarium specimens, whose chromosomal counts cannot be made, these features are obvious. Therefore, a key on which to differentiate the two must be a highly artificial one. *P. pubescens* (n = 10) is clearly distinct from the other two species because of its pubescent leaves. The appearance of diploid clones within the range of *P. canaliculatum* is also noted, and this observation brings up the fact that polyploidy may not be the complete answer to the question of speciation. Breeding studies will be made in the future in the hope that they may cast additional light on the question.

HOSKINS, J. H., and A. T. CROSS, University of Cincinnati, Cincinnati, Ohio. *A consideration of several species of the fructification of Bothrodendron*.—Investigations on a large number of Iowa coal balls have disclosed some excellent, preserved, fragments of *Bothrodendron* fructifications. A review of the principal characteristics is undertaken in order to justify proper designation of species.

HOSKINS, J. H., and A. T. CROSS, University of Cincinnati, Cincinnati, Ohio. *The structure and affinities of a new species of Sphenophyllotachys*.—A portion of a petrified *Sphenophyllum* fructification found in an Iowa coal ball has been studied and is described as a new species. The specific distinction is based on the nature of the arrangement of the sporangia. Three unbranched sporangiophores of unequal length arise at slightly

different points near the base of the bract bears a single sporangium placed linearly on the surface of the bract. Thus in longitudinal section through the strobilus, three sporangia may be seen upon the adaxial surface of each bract. Affinities with *S. Dawsoni* are clear, but since we question the homogeneity and validity of that species, we cannot justify the inclusion of our specimen within it.

HULBARY, ROBERT L., Columbia University, New York, N. Y. *The three dimensional shape of cortical cells in the stem of Elodea*.—In the cortex of *Elodea densa* (*Anacharis densa* Victorin), the shape of cells in the internodes is influenced by the presence of large air canals. These cells are all elongated along the longitudinal axis of the stem and nearly every one abuts upon either 2 or 3 of the air canals that run the full length of each internode. The cells are regularly arranged in rows surrounding the air spaces. The average number of sides per cell for 3200 cells taken from 27 consecutive internodes, starting 6 mm. back of the stem apex, was 8.81. Of 500 cells studied more intensively, which averaged 8.85 faces, 195 were 8-sided with the others ranging from six sides to fourteen. There was a total of 1425 facets on the 500 cells and of these 64 per cent were quadrilaterals, 19 per cent were hexagons, and 13 per cent were pentagons. The average length of the cells studied varied from 45 microns in an internode 6 mm. back of the apex to 331 microns in the 27th internode or 17 cm. back of the apex, where the cortex is mature. The number of sides per cell remains fairly constant for each internode throughout the 17 cm. of *Elodea* stem studied. The average number of sides per cell for 100 cells in the first internode back of the stem apex is 8.85 and for 100 cells in the 27th internode 8.82. Apparently the shape of cortical cells of the internodes of *Elodea* is determined near the very apex of the stem—within the first 6 mm.—at the same time that the elongate air spaces are formed. Increase in cell size from one internode to the next does not result in an increase in the number of contacts per cell.

HUNT, KENNETH W., College of Charleston, Charleston, S. C. *Floating mats on a southeastern coastal plain reservoir*.—The plant succession in floating mats on a reservoir at Charleston, S. C., is described. It differs greatly from the familiar northern bog development, having *Jussiaea grandiflora* and *Achyranthes philoxeroides* forming the pioneer zone, and a variety of southern mesophytes occupying the interior. It is believed that this succession is unusual for the southeastern coastal plain, where due to the fluctuating water-table xeric shrub bogs normally develop. This may suggest what should be expected when reservoirs with stabilized water levels are constructed in the southeast. Data on the history and composition of the reservoir are supplied.

JOHNSON, MARION A., Rutgers University, New Brunswick, N. J. *Zonal structure of the shoot apex of Encephalartos*.—Six species of *Encephalartos*

have been examined. The shoot apex in all six species is broadly cone-shaped or mound-like and may terminate in a plateau about twenty cells in diameter. The summit is occupied by a zone of initiation which contributes to surface growth and to an underlying zone of central mother cells. The central mother cells are characterized by their large size, conspicuous vacuoles and complex cell pattern. Radiating files of active cells arise from this zone. The lateral files, together with the superficial layer and its periclinal derivatives, constitute a peripheral meristem. A rib-meristem, which produces the massive pith, is derived from the base of the central mother cell zone.

KARLING, JOHN S., Columbia University, New York, N. Y. *Two new genera of parasites and their bearing on the phylogeny of the lower fungi*.

—These genera parasitize the marine algae *Pyraliella* and *Ectocarpus* and occur in abundance in the vicinity of Beaufort, North Carolina. One of the parasites has an animal- or *Proteomyxa*-like type of nutrition (engulfing solid food particles and digesting them in vacuoles) and a life cycle identical to that of the *Plasmodiophorales* with anteriorly biflagellate heterocont zoospores. It combines thus the characteristics of the *Proteomyxa* and *Plasmodiophorales* and suggests that these two groups of lower organisms may be closely related. The other parasite is similar in structure and development to the olpidoid chytrids but has anteriorly uniflagellate zoospores which excludes it from the *Chytridiales* as this order is now generally recognized.

LANGDON, LADAMA M., Goucher College, Baltimore, Md. *On the structure and development of the cupule in the Fagaceae*.—The indehiscent 1-seeded fruit, tricarpetate flowers, and the special involucre are distinctive of the *Fagaceae*, with considerable debate as to the nature of the involucre, whether it is composed of the fused bracteoles of the little dichasium, or represents sterile scales of a condensed cone-like inflorescence, or is a wholly new outgrowth of the subfloral axis. Developmental and anatomical studies of species of different genera of this family, including *Quercus*, *Fagus*, *Castanea*, *Castanopsis* and *Nothofagus* emphasize the essentially uniform nature of this structure, varied as its external features may be, and reveal it as a ring-like overgrowth of the subfloral axis which more or less completely incloses the 1-3 flowered female inflorescence, and bears numerous acropetally developed scales, variously modified in the different genera. A noteworthy resemblance to the gland-bearing husk enveloping seeds of the *Lagenostomales* is seen in the gland-adorned segments of involucre enclosing the female florets and nutlets of certain species of *Nothofagus*.

LEONIAN, LEON H., and VIRGIL GREENE LILLY, West Virginia University, Morgantown, W. Va. *The "unknown factor" in the growth of yeast*.—"Substances of unknown nature present in liver and yeast extracts play an important role in promoting rapid growth." This was the conclusion of Williams, Eakin

and Snell who were the first to study the relationship of five B vitamins to the growth of yeasts. But now we have found that insofar as some ten strains of yeasts are concerned, this unknown factor is not qualitative in nature but quantitative. The liver or yeast extracts do not furnish new growth factors but merely increase the amount of the well known vitamins and thus bring about much greater yields. Williams et al. used 5 micrograms of inositol per ml, 0.04 micrograms of thiamin, 0.0001 micrograms of biotin, 0.006 micrograms of pantothenic acid, and 0.04 micrograms of pyridoxin. We increased inositol to 10 micrograms, thiamin to 0.1 micrograms, biotin to 0.001 microgram, pantothenic acid to 0.1 microgram, and pyridoxin to 0.1 microgram. This brought about sharp increases in the yield of all ten yeasts; addition of yeast extract failed to bring about significant increases. Now it should be possible to use yeasts in microbiological assays without fear of complicating, unknown factors.

LEVINE, MICHAEL, Montefiore Hospital, New York City, N. Y. *The effects of x-rays on "colchicine tumors" on the root tips of the common onion.*—The root tips of onion bulbs (*Allium cepa* var. *yellow globe* and var. *Brigham Yellow Globe*) immersed in .01 per cent solution of colchicine in tap water develop after 48 hours characteristic swellings, "colchicine tumors." The return of these bulbs to tap water is followed in 48 to 96 hours by the resumption of growth of the tips of the "tumors." The exposure of these roots to x-rays (900r, 1500r, or 3000r) prior to their return to water inhibits their growth. Cytological studies of the roots exposed to .01 per cent colchicine for periods from 18 to 140 hours and to the larger doses of x-rays show that these combined treatments impair permanently the ability of the cells to divide. "Tumors," twenty-four hours in water after colchicine and x-ray treatments fail to reveal any evidence of cell division. Later stages show lethal effects characterized by undifferentiated nuclear masses and absence of cytoplasm. The treated bulbs were kept in water for twenty or more days after treatments. Control studies of the effects of water, colchicine, and x-rays were made concurrently. These results suggest that colchicine and x-rays not only injure cells in the "metaphase" stage but also the nuclei in the resting stage. These results suggest further, that some spontaneous tumors of animals and cancer in man may respond more advantageously to x-rays when preceded by suitable doses of colchicine.

MANNING, WAYNE E., Northampton, Mass. *A leaf character for shagbark hickory.*—The leaves of young and mature trees of *Carya ovata* can be distinguished from the leaves of all other northeastern hickories by one or two dense tufts of hairs on the upper part of each serration; these are usually accompanied by a ciliation of single or fascicled hairs. On seedlings and small saplings of this species the leaf margins are almost uniformly ciliate as in those

of the mockernut, the king nut hickory, and very young pignuts.

MARIE-VICTORIN, FR., University of Montreal, Montreal, Canada. *A new American Dracaena.*—Only one true *Dracaena* was known in the Western hemisphere. A second species, collected several times, but unrecognized on account of its being sterile, grows in the province of Oriente, Cuba. It is a member of the *Pinus cubensis* association and its range is restricted to the serpentine rocks and iron soils of the pinelands of Moa. The species, which seems the closest approach to *Dracaena Draco* of the Canary Islands, is here described as *Dracaena cubensis*.

MARVIN, JAMES W., University of Vermont, Burlington, Vt. *Cell shape and cell volume relations in the pith of Eupatorium perfoliatum.*—The number of faces on compressed spheres of uniform size when aggregated to form polyhedra approximates 14. Matzke has shown that when spheres of different sizes are compressed the smaller have less than 14 and the larger more than 14 faces. Fifty small and fifty large cells from a mass of *Eupatorium perfoliatum* pith were selected and their shape determined from three-dimensional models. The small cells averaged 10.8 faces and the large cells 16.2 faces.

MATZKE, EDWIN B., Columbia University, New York, N. Y. *The role of interfacial tensions in cell shape determination.*—Three dimensional shapes occurring in individual bubbles in a mass of foam are compared with three dimensional shapes occurring in cells in undifferentiated tissues. Similarities and differences are pointed out, and the relative importance of such tensions in cell shape determination is analyzed.

MATZKE, EDWIN B., and ROBERT L. HULBARY, Columbia University, New York, N. Y. *Wood characters and species characters in the white pines of commerce.*—A study has been made of the pits of the ray parenchyma cells in contact with the tracheids in the northern white pine, *Pinus strobus*, in the western or Idaho white pine, *P. monticola*, and in the sugar pine, *P. lambertiana*. Data have been assembled on the size, shape, and area of more than 200 such pits. They are more commonly large and oblong in *P. strobus*, smaller and lemon-shaped in *P. lambertiana*, and intermediate in *P. monticola*. The range of variation is pointed out, and its bearing on the subject of species relationships is suggested.

MERRILL, ELMER D., Arnold Arboretum, Jamaica Plain, Mass. *Some aspects of Rafinesque's botanical work.*—A brief summary of Rafinesque's publications and steps now being taken to elucidate his work more thoroughly. He actually proposed in the neighborhood of 3000 generic names as new, infinitely more than any other botanist, for even Linnaeus utilized less than 1600. Only a small proportion of Rafinesque's names were recognized by his contemporaries and successors. A critical examination of all known Rafinesque botanical papers, issued between 1804 and 1840, indicates that there are

apparently between 1200 and 1500 Rafinesque plant names in all categories—genera, subgenera, and species—that have never been listed in our standard indices. It is proposed eventually to prepare and issue a comprehensive "Index Rafinesquianus" which is planned to include all plant names proposed by him, with reductions where possible.

MERRILL, E. D., Arnold Arboretum, Jamaica Plain, Mass. *American weeds in the old world tropics*.—A consideration of the periods in which weeds, together with economic plants, were originally introduced into the Indo-Malaysian region, their American sources, and an attempt to explain the Napoleonic ambitions indicated by many of these alien plants when once established in their new homes. There is no evidence available that would indicate any pantropical distribution of these pest plants previous to Magellan's voyage in 1520. In most parts of the Indo-Malaysian region the dominant weeds today are those species of American origin, the great centers of origin apparently being Mexico and the eastern bulge of Brazil.

METZNER, JEROME, Columbia University, New York, N. Y. *Recent studies of Volvox carteri (Stein)*.—This relatively rare species of *Volvox* has been described under various names by workers in widely separated parts of the world. The present study involves careful investigation into the details of the life cycle. A comprehensive photomicrographic record of the living organism and of its morphology was made. The development of a daughter colony and the germination of the oospore into a juvenile colony are illustrated and discussed.

MEYER, JAMES R., The Blandy Experimental Farm, University of Virginia, Boyce, Va. *Cytogenetic studies of Phlox*.—Eighteen species of *Phlox* from Eastern North America, involving 276 plants, have been studied cytologically. A random examination of named horticultural varieties and plants from the wild has shown: 76.7 per cent diploid ($2n = 14$); 20.7 per cent with from 1 to 13 small, centric fragment chromosomes ($2n = 14 + 1-13$ ff.), 1.9 per cent tetraploid ($2n = 28$), 0.4 per cent (1 individual) triploid ($2n = 21$), and 0.4 per cent with 16 chromosomes ($2n = 16$). The centric fragments do not seem important, since they may vary in number from none to 13 per cell within one plant without noticeably affecting either cell viability or the morphology of the plant. *Phlox Buckleyi* and 4 of the 24 *P. subulata* plants are tetraploid. *P. suffruticosa* Miss Lingard is a triploid. It was found that, within *P. subulata*, tetraploids do not always have larger cells and organs than do the diploids, but when a pure strain of *P. Drummondii* was colchicine-treated, the resulting tetraploid had larger cells and organs than the diploid. Idiograms and meiotic studies have shown that intra-specific and inter-specific differences in chromosome morphology and structure are common.

MILLER, HELENA A., Harvard Biological Laboratories, Cambridge, Mass. *Development of tissues in embryos of Phlox*.—The development of em-

bryos of *Phlox Drummondii* were studied from the first divisions of the zygote to the embryo of the mature seed. Sections of early proembryos show an axial symmetry and a cellular homogeneity. Sections of later proembryos show regions of varying staining capacities: a dark-staining central core of elongate cells, a surrounding region of light-staining cells and an enclosing potential epidermal layer. The axially symmetrical proembryos become bilateral with the appearance of the cotyledons on or about the seventh day. As the cotyledons expand from then to about the thirtieth day the above mentioned core of elongate cells becomes extended uninterruptedly into them as characteristic procambial leaf strands suggesting the procambial nature of the original core. The ground meristem of the earlier proembryo is also extended as the cotyledons develop. During this same time the outer layer of potential epidermis divides periclinally in the basal region forming the root cap. As the cap becomes complete from the fifteenth to the twentieth day the suspensor disintegrates and disappears. Interior to the root cap in the basal region, a hypocotyl meristem appears which by its activity extends the procambium, ground meristem, and epidermis of the hypocotyl. By the activity of a rib meristem at this hypocotyl meristem, the earlier central core of procambium becomes a cylinder. In the embryo of the mature seed, adaxial cells in the procambial strand of the upper half of the cotyledons have become mature protoxylem; meanwhile certain abaxial procambial cells in the basal region of the cotyledons show the characteristics of immature sieve tubes.

MILLER, LAWRENCE P., Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y. *Sugar components of β -glycosides formed in plants through treatment with chemicals*.—Many of the less common sugars that have been shown to be present in plants occur as components of glycosides. Naturally occurring glycosides are found only in certain species and are often of complex structure and identification of the sugar component is frequently difficult. Experiments in which plants were treated with chemicals containing an hydroxyl or potential hydroxyl group (such as ethylene chlorohydrin, *o*-chlorophenol or chloral hydrate) have shown that many species including some not known to contain glycosides normally, will form β -glycosides if furnished with chemicals which can serve as aglucons. Such glycosides have been obtained in crystalline form and identified through the preparation of the corresponding synthetic compounds from 15 species of higher plants belonging to 9 families. Frequently the same aglucon will unite with more than one sugar in the same species and even in the same plant organ. As would be expected, the sugar most commonly utilized for glycoside formation was D-glucose; however, with all the solanaceous species tested some gentiobioside was also formed, although gentiobiose was not previously known to occur in this family. Some of the species studied were able to withstand the absorption of surprising-

ly large amounts of added chemical without serious injury. As a result the glycosides comprised a major constituent, quantitatively, of the plant tissues produced. Tobacco leaves were obtained which contained up to 12 per cent on a dry weight basis of a mixture of β 2-trichloroethyl-D-glucosides and β 2-trichloroethylgentiobioside.

MURPHY, JOHN B., De Paul University, Chicago, Ill. *The influence of magnetic fields on seed germination.*—The influence of magnetic fields was studied on several different species of seeds in the process of germination. In the majority of cases the seeds showed a definite acceleration in germination and in several instances produced a more hardy type of plant than the plants not influenced by magnetic forces. The initial vigor often seemed to subside after the plant reached a growth of several weeks. Some of the plants influenced by the magnets reached maturity before the control plants. The permanent magnets used were steel magnets of varying forces. Electromagnets were also employed and a third type of magnet was derived from the field about wires through which an electric current flowed. The type of magnet used did not seem to be very important. The electromagnet was the least desirable because it affected the temperature of the soil. Some possible effects of the magnetic influence on cell activity were studied. The experiments are not conclusive but are suggested with the hope of stimulating a more extensive and complete study of the subject.

NEAL, LOUISE A., University of Colorado, Boulder, Colo. *Germination and growth of certain plant species as influenced by seed treatment with growth substances.*—The germination and later growth of eleven plant species as influenced by the application of growth-promoting substances to their seeds is reported in this study. The percentage of germination was increased in Penstemon, Verbena, Vinca, Antirrhinum, Petunia, and the Scarlet O'Hara morning glory by the use of Hormodin Powder No. 1. Mixtures of indole-3-acetic and α -naphthaleneacetic acids in dust form stimulated germination in the first three species mentioned above, and also in Cleome and the moonflower; the use of indole-3-acetic alone was favorable not only for these five species but also for Coleus, Petunia, and the blue Japanese morning glory. When only α -naphthaleneacetic was used germination was increased in but two species, Verbena and Vinca. Vegetative growth was stimulated and dry weight increased in snapdragons treated with all the chemicals with the exception of the mixture of indole-3-acetic and α -naphthaleneacetic acids (100 mg./l.); in barley, by all substances with exception of indole-3-acetic acid (10 mg./l.). Blossoming was hastened in snapdragons by seed treatment with indole-3-acetic acid in either solution or in the dust form; in Cleome, by the use of Hormodin Powder No. 1. More striking results in increasing germination percentage and vegetative growth were obtained from the use of mixtures of indole-3-acetic and α -naphthaleneacetic

acids in the dust form than by the use of the substances alone.

NEWCOMB, ELDON H., University of Missouri, Columbia, Mo. *A study of the respiration of the large oak apple gall.*—The galls produced by *Amphibolips confluentis* Harris on the leaves of Red Oak (*Quercus borealis* var. *maxima*) contain 370 times fewer cells per unit volume of tissue than do normal leaves during the month of May. The oxygen uptake per cell is also more than 40 times greater in the gall tissue. The respiratory quotients in both cases were unity. The respiratory rate of both gall and normal leaf tissue falls as the organs develop and ultimately loses its sensitivity to cyanide and azide. An insensitive residual respiration remains in both cases but the change comes earlier and more abruptly in the gall tissues. Both gall and normal leaf tissues carry on fermentation in the absence of oxygen, but the rate of carbon dioxide evolution per cell is many times greater in the former. Galls differ from normal leaves in producing appreciable amounts of organic acids which tend to accumulate in the tissues.

PENNEL, F. W., Academy of Natural Sciences, Philadelphia, Pa. *Zones of plant life in the Colombian Andes.*

PIERCE, JOHN H., New York Botanical Garden, New York, N. Y. *The status of the genus Lophotocarpus.*—For many years the name *Lophotocarpus* has been applied to United States plants of the family *Alismaceae* which actually belong to the genus *Sagittaria*. In recent literature an incorrect type species has been cited for the genus. If *Lophotocarpus* is to be maintained as a genus, the correct type species limits the application of the name to plants not found in the United States.

PRICE, WINSTON, and PAUL J. ALLEN, University of Pennsylvania, Philadelphia, Pa. *Studies on respiration and flow in the myxomycete, Physarum polycephalum.*—The Q_{O_2} , based on the fresh weight and on O_2 consumption determined with a Fenn respirometer, has a value as high as 23.0 with an average of 15.0, this rate remaining constant for 21½ days. The Q_{O_2} varies with the amount of tissue used. Below 30 mg. there is injury and the rate declines sharply with smaller amounts of tissue. The R. Q. is about 0.8. Anaerobic CO_2 production is 1/3 the aerobic, indicating the absence of a Pasteur reaction. There is only a small reduction in respiration when O_2 tension is reduced to 5 per cent, but below 5 per cent it drops off rapidly to a value of less than 10 per cent of normal at 0.3 per cent O_2 without stopping the protoplasmic streaming. The streaming is therefore independent of a very large percentage of the energy released in aerobic respiration. Furthermore, 60 per cent of the O_2 consumption is inhibited by M/1000 KCN, which has no effect on flow. CO up to 95 per cent has no effect on respiration except that due to the reduction in O_2 tension, indicating the absence of cytochrome oxidase or polyphenol oxidase. NaN_3 inhibits respiration to about the same extent as KCN. Azide, how-

ever, reversibly inhibits streaming in concentrations of M/1000 to M/3000. M/20 malonate and M/500 pyrophosphate do not inhibit respiration, indicating the absence of succinic dehydrogenase. NaF and ethyl urethane inhibit respiration only slightly. None of these four poisons affect flow. Experiments with iodoacetate are in progress. The respiration is indifferent to the addition of M/20 Na succinate, fumarate, malate, lactate and pyruvate. The plasmodium disintegrates immediately when Na citrate is added. Vitamins B₁, B₂ and C do not affect respiration, but it is increased on addition of 2 gamma of nicotinic acid /ml.

REED, CLYDE F., Harvard University, Cambridge, Mass. *Comparative morphology of spores in ferns and its relationship to taxonomy*.—A survey of the spores of over 4500 species of ferns was made, and a correlation of this and other morphological data, such as cellular, stomatal and tracheary, has revealed many new phylogenetic relationships, heretofore unrealized. This necessitates a reclassification of the ferns into a more natural sequence, to be published as a series of books: History and Philosophy of Fern Taxonomy; Morphology of Ferns; a Synopsis Filicum, with descriptions of all known species, varieties and forms; Phytogeography, with maps of the genera and families; Ecology of the Ferns, including physiological data on growth; Phylogeny of the Ferns, including evidence from the fossils; a new Index Filicum, to include citations to genera, species, varieties and forms. In spores, the characters of the perispore and exospore, the size and shape, the color and the nuclear relationship afford family, generic and often species differences.

REID, MARY E., National Institute of Health, U. S. Public Health Service, Bethesda, Md. *Biological interrelations of ascorbic acid and calcium*.—Results of studies with plants and animals from many laboratories suggest that ascorbic acid and calcium are closely involved in functioning at cell surfaces and in the formation of special types of intercellular substances. The evidence in support of this concept is summarized.

RICKETT, H. W., New York Botanical Garden, New York, N. Y. *Cymose and racemose inflorescences*.—Some so-called racemes originate with a terminal flower in the axil of whose prophyll arises a shoot which simulates a continuation of the main axis. A repetition produces a sympodium whose lowest flowers open earliest. Similar statements may be made about various "umbels," "heads," and "spikes." The order of flowering therefore seems unsatisfactory as defining types of inflorescences; the terms monopodial and sympodial are suggested in place of racemose and cymose. In some racemes the terminal flower is the first to open. Order of flowering has therefore no necessary connection with morphology. A branch terminated by a flower, beneath which similar floriferous branches may appear, is held to be primitive. From such a panicle

cymes, corymbs, racemes, and spikes may have been derived.

ROBERTS, EDITH A., Vassar College, Poughkeepsie, N. Y. *The structure of chloroplasts, chromoplasts, leucoplasts and carotin "crystals" and their relationship to cellulose "particles" and colloidal carbon*.—The photomicrographs published in 1940 show that chloroplasts are composed of units 1 micron in size and these are termed plastid granules. Work upon the chromoplasts, leucoplasts and carotin "crystals" show that they too are composed of units approximately 1 micron in size. These units are held together by protoplasmic strands forming the respective plastid bodies and they, in turn, are held by strands in the protoplasmic matrix. The granule bodies are themselves composed of smaller units—about 0.5 microns in size—termed *primary* granules, and these, in turn, are composed of still smaller units—about 0.25 microns in size—termed *secondary* granules. The secondary granules are composed of units about 0.1 microns in diameter—called *tertiary* granules. These units are made up of *quaternary* granules—0.04 microns in diameter, and again these are formed of 0.02 micron units or *quintary* granules. In leucoplasts filled with starch, the quintary unit is subdivided into *senary* granules—0.01 microns in diameter. In "cellulose particles" and in colloidal carbon, there is a unit comparable to this senary granule. The "cellulose particle" is shown to be composed of the same primary, secondary, tertiary quaternary, quintary, and senary granules. This senary granule is also in the size realm of the viruses and suggests a possible relationship. During this investigation, the carotin "crystals" were easily separated into the 1 micron granule unit, as were the sheets of carotin embedded in the walls of the carrot root. If "all types of coal represent stages in the progressive disintegration or carbonization of plant tissue," then it is quite possible that in the building of plant tissue there is a basic design and that the larger units—"cellulose particles" or granules—are a repetitive pattern of the lowest units or the smallest colloidal carbon particle and the granules or "cellulose particles" make up the plastids and tissues of the plant.

SATINA, SOPHIA, and A. F. BLAKESLEE, Smith College, Northampton, Mass. *Initiation and development of carpels determined by periclinal chimeras in Datura stramonium*.—Periclinal chimeras were used in studying development and structure of carpels which form a syncarpous pistil with axile placentation. Initiation and early development of the two carpellary primordia depends primarily on activity of the innermost third germ layer. At early stages the first and second germ layers are each only one cell thick. Two opposed concave carpel walls develop from the primordia. A portion of the central axis remaining within the carpel primordia grows continuously to form an elongated column. The septum and false septum with placental tissue differentiates from portions of the axis. Their early

growth depends on activity of the third germ layer. The upper regions where the carpel walls coalesce and unite with the septum are formed predominantly by cells from the second layer. This occurs in later stages. The larger basal part of the ovary continues to grow from the activity of the cells of the third germ layer. Terminal growth of carpel walls forms the style and stigma. Cortex of the style is formed from cells of the second germ layer; vascular system from cells of the third germ layer; and transmitting tissue in the style and stigma from cells of the first germ layer. Early development of the carpel suggests that it is axial in origin.

SINNOTT, EDMUND W., and ROBERT BLOCH, Yale University, New Haven, Conn. *Fiber development in Luffa, the sponge gourd.*—In a considerable number of lines of *Luffa cylindrica* and *L. acutangula* a study was made of the development of the anastomosing network of fibrous strands which gives these plants their economic importance. The lines were found to differ markedly not only in the size and shape of the fruit but in the character of the fiber system. Its strands vary from 0.1 mm in diameter to 0.5 mm or more. The network may be relatively loose or much more compact. The diameter of the peripheral system of strands—the “wall” of the sponge—varies from 2 mm to 8 mm in different lines. The outer strands tend to run transversely to the fruit axis and the inner ones parallel to it. Differentiation of strands begins very nearly in ovary development and the entire framework is usually established by the time of anthesis. Each strand possesses a small core of phloem elements, which in the larger ones are accompanied by a few xylem cells. The bulk of the strand consists of much elongated heavily lignified sclerenchyma fibers which are very difficult to macerate. These range from 700 micra to well over 3000 micra in length and from 25 micra to 50 micra in diameter. Lignification of fibers begins first in strands near the axis of the fruit. Fruits developing parthenocarpically after treatment with various growth substances show essentially the same fiber development as do normal fruits.

SMITH, A. C., Arnold Arboretum, Jamaica Plain, Mass. *Geographic distribution and speciation in the Winteraceae.*—As now constituted, the Winteraceae is a family of 6 genera and about 88 species, occurring in the Australasian and Malayan regions and also in America south of Mexico. The criteria used for generic delimitation in the family are discussed. The genus *Drimys* is an interesting illustration of bicentric-palaeantarctic distribution; the probable method of differentiation in *Drimys* in America is outlined.

SMITH, A. C., Arnold Arboretum, Jamaica Plain, Mass. *Vegetational zones of northern South America.*—The region under consideration is the portion of South America from the Amazonian plain and Bolivia northward, with an area of about 3,500,000 square miles. This region presents a vast diversity of habitats, with elevations up to more than

6000 m., with a great range of temperature, and with rainfall varying from essentially none to more than 300 inches per year. Probably about 50,000 species of flowering plants and ferns occur in this area, parts of which are botanically unknown. Altitudinal floristic zonation is obvious in northern South America; the arbitrary elevations of about 1000 m., 2500 m., 3500 m., and 5000 m. may be taken to represent the upper limits of the tropical, subtropical, temperate, and alpine zones respectively. In each of these major zones we find a multitude of minor divisions, dependent upon such factors as local conditions pertaining to rainfall, humidity, topography, and soil. The alpine meadows of the northern Andes are of especial interest, because of the pronounced endemism of their vegetation. It seems probable that only three major elements have entered into the composition of the flora of northern South America. By far the largest of these is a pantropical element which probably indicates a common, but remote, ancestry for the flora of South America and Africa. A second element, represented by certain temperate groups of plants suggestive of the flora of North America, has presumably travelled southward from a boreal center of dispersal. A third element indicates a relationship between the floras of South America and Australia, suggesting an ancient Antarctic connection.

STADLER, L. J., U. S. Department of Agriculture and University of Missouri, Columbia, Mo. *Gene action in anthocyanin synthesis in maize.*—Excised roots of certain strains of maize, cultured on agar with added mineral nutrients and glucose, synthesize anthocyanin. The genes A_1 , A_2 , and r^+ , or suitable alleles, are essential to the synthesis. With genotypes $a_1 (A_2 r^+)$ and $a_2 (A_1 r^+)$, an anthoxanthin pigment is synthesized instead of anthocyanin. Certain alleles of r^+ result in the synthesis of different quantities of anthocyanin, and with $r^s (A_1 A_2)$ no anthocyanin is produced.—The same 3 genes are essential for anthocyanin production in the vegetative organs of normally grown plants, except that r^+ is not essential in the presence of B . Genotypes $B (r^s A_1 A_2)$ and $r^+ (b A_1 A_2)$ produce the same anthocyanin, and in those tissues which may be pigmented by the action of either gene, the quantity of anthocyanin produced is in general greater with B than with r^{ch} , the r^+ allele most effective in plant pigmentation.—Excised leaf sections of genotype $r^{ch} (b A_1 A_2)$, floated on glucose solution, produce anthocyanin abundantly in epidermal cells. The amount of anthocyanin produced varies with the glucose concentration, and under the standard conditions used the reaction is sensitive to concentrations of the order of $10^{-3}M$. Various r^+ alleles differ in quantity of anthocyanin produced at a given glucose concentration. In plants capable of anthocyanin synthesis through the action of B instead of r^+ (genotype $B r^s A_1 A_2$) the excised leaf reaction is wholly negative, regardless of the concentration of glucose.—The excised leaf reaction is inhibited by dinitrophenol. Certain other sugars (fructose, galactose,

xylose, lyxose) and certain sugar derivatives (sorbitol, glyceric acid, glyceraldehyde, hydroxypyruvic aldehyde) may be substituted for glucose with positive effects, though in some cases with lowered effectiveness. None of these results in anthocyanin production in genotypes a_1 , a_2 , or r^2 .

STEWART, RALPH R., New York Botanical Garden, New York, N. Y. *The flora of Kashmir and its relationships*.—Kashmir is the northern-most part of India and stretches roughly from 32' to 36' north and from 74' to 78' east. Except for the famous Vale of Kashmir it is all mountainous, containing some of the most rugged country in the world. There is a semi-tropical flora in the foothills and there are all the intermediate steps to an alpine flora of great variety. No flora has yet been published but about 2,200 flowering plants and 100 species of ferns have been collected. The flora contains a number of diverse elements. Representatives of the desert flora which stretches east from Arabia are found in the Jhelum and Indus Valleys. The subtropical plants come from the southeast and some have a distribution which reaches to the Philippines. The temperate and alpine floras, as might be expected, have both eastern and western elements. Behind the main Himalayan Range there is hardly any rain and the flora is Tibetan or Central Asian. In addition there are quite a few endemic species.

STRUCKMEYER, B. ESTHER, University of Wisconsin, Madison, Wis. *Further studies on the micromincineration of plant material*.—Previous observations have shown that a difference in mineral residue exists in stems of vegetative and flowering plants. From these observations several problems arose which were investigated. Considerable difficulty was encountered in obtaining incinerated sections in which the tissue was not displaced or curled. After trial of numerous adhesives, "Nevillite 123" was found to be satisfactory as it prevented the thick walled material from shivering and shrinking. By the use of this adhesive the mineral inclusions retained their position during incineration. The use of either absolute alcohol, absolute alcohol and formalin, cellosolve, or dioxan as fixing agents showed almost no difference in the amount of mineral residue. Dioxan appeared to have some shrinking effect on the tissue. The incineration of vegetative stems from several different plants of a species showed a similar mineral pattern. A difference in the mineral pattern became apparent soon after plants were placed in an environment conducive to flowering. Identification of the minerals in the stems is being made with histological reagents employing micropipettes and a micromanipulator.

SVENSON, HENRY K., Brooklyn Botanic Garden, Brooklyn, N. Y. *Relation of the Galapagos flora to that of the mainland*.—Climatic conditions on the Galapagos Islands are practically identical with those of the dry coast of Ecuador. A number of species supposedly endemic to the Galapagos are found on this coast, and some of the widespread species show a similar type of stunted growth in the Galapagos Islands and on

the desert mainland. This climatic area includes the Galapagos Islands, the southern coast of Ecuador, and the northwest coast of Peru. The flora of the Galapagos Islands is also connected with the dry areas of western Mexico, northern Colombia, and the West Indies.

TRYON, R. M., JR., Dartmouth College, Hanover, N. H. *Dynamic phytogeography of the fern genus Doryopteris*.—*Doryopteris* is primarily a New World genus. Of the 26 species only 5 occur in the Old World and these are not considered here. Species evolution in the genus probably started in the general region of northern Argentina and Paraguay. The 3 most primitive species occupy this area and none of the 7 most highly derived species occur in the region. From this general area, species moved in two directions. One route was up the coast of southeastern Brazil as far as the state of Parahyba, with an outpost on Ilha Trindade. The other path of migration was through Bolivia and up the Cordillera to Colombia, then eastward through Venezuela to British Guiana, with outposts in the West Indies, central Mexico, and the Galapagos Islands. These routes of migration were determined by arranging the species in a phylogenetic series and then successively comparing the ranges. Section *Eudoryopteris* has a broad distribution with relatively few, distinct, widely ranging species. It went through its species evolution rather early. Section *Lytoneuron* is not as widely distributed and has many, less distinct, local species. The species of this section evolved more recently. Its center of evolution is in or near the state of Rio de Janeiro. Of the 12 species in the section, 10 grow in the states of Rio de Janeiro and São Paulo, and 5 of them are endemic to that area.

VAN FLEET, D.S., Heidelberg College, Tiffin, Ohio. *The influence of the morphological behavior of unsaturated fat oxidases on the development and function of the endodermis*.—The unsaturated fatty acid oxidation system of the endodermis may be identified as a series of chain reactions catalyzed by metal salts and various alkaline pro-oxidants. The behavior of the system is modified by local differences in intensity of oxidation in stele and cortex so that several distinct types of morphological and functional endodermal cells appear. The Casparian strip and centripetal deposition are associated with partial and incomplete oxidation and the polymerization of degradational products. The peculiar morphological appearance of the "gap" cell is a result of oxidation without the accumulation of oxidized substances which are soluble and diffusible. The intense oxybiosis in some "gap" cells is causally related to their function as water passage cells. The starch sheath is characterized by the presence of alkali labile antioxidants which prevent oxidative decomposition of fats. These fats accumulate and inhibit diastatic action so that starch of an isotropic nature is retained. Sodium selenite, and other alkali salts, as reported previously, will inhibit oxidation in other oxidase systems but will accelerate oxida-

tion in the endodermis through the destruction of alkali labile antioxidants. By means of selenite and phosphate buffers (pH 7.2-7.8) it is possible to isolate histologically the unsaturated fat oxidase system. Thus the tissue having the morphological position of the endodermis, without any of the accepted configurations and standards for this tissue, may be identified by virtue of its functional behavior as well as by position. It is possible to demonstrate a functional and morphological endodermis in many stems reported earlier to be without this tissue.

VERDOORN, FRANS, Arnold Arboretum, Jamaica Plain, Mass. *The centenary of the "Botanische Zeitung."*—A short account of the early history of the "Botanische Zeitung," one of the first scientific and professional botanical journals, its influence, and its successors. A discussion of the task of botanical journals today, with special reference to the promotion of professional and international relations in the plant sciences.

WALLACE, RAYMOND H., University of Connecticut, Storrs, Conn. *A simple and effective automatic voltage regulator.*—A simple and effective voltage regulator suitable for many laboratory uses is described. It consists essentially of a transformer of the Variac type which is held on balance to the voltage desired by means of two small thyatron tubes that activate a reversible motor. The general characteristics of the instrument are as follows: amperage range, 5 to 50 depending upon transformer used; accuracy of control, plus or minus $\frac{1}{2}$ volt in 110; speed of correction, one to five seconds for 20 volts variation; wave form, no distortion; range of output voltage for which regulator can be set, 105 to 120, for input voltage variation from 90 to 130; accuracy with variable load, equally accurate for no load and for full load for which transformer is built; dependability, has run continuously for 14 months with only nominal attention. The cost of all materials for a 5 ampere model is about \$26.00. List of materials, instructions and full sized blueprints for the construction of the control are available.

WARMKE, H. E., Carnegie Institution, Cold Spring Harbor, N. Y. *The cytology and breeding behavior of the Russian dandelion, Taraxacum kok-saghyz.*—The chromosome number of *T. kok-saghyz* is $n = 8$; $2n = 16$, which establishes this species as a basic diploid in the genus. One pair of chromosomes bears large satellites. Plants protected from insects rarely set seed, but are fully fertile out of doors or when manually cross-pollinated, indicating a high degree of self-sterility. This species shows no evidence of apomixis, which is usual for the common polyploid members of the genus. Gamete formation follows the normal sexual pattern on both male and female sides: microsporogenesis is regular and produces a high percentage of good pollen. The macrospore mother cell undergoes a reduction division to form a linear tetrad of macrospores, the chalazal one of which usually becomes functional and forms the typical 7-celled macrogametophyte.

The above facts indicate *T. kok-saghyz* to be a normal sexual diploid and open the way for selection and breeding experiments to increase rubber content.

WEATHERWAX, PAUL, Indiana University, Bloomington, Ind. *Morphology of the spikelet of Dryzopsis hymenoides.*—The vascular bundles of the two lateral lodicules arise acropetally. The single bundle of the third (median) lodicule differentiates both acropetally and basipetally and fails to make connection with the central vascular system of the flower. This has an interesting bearing upon some recent theories as to differences between vegetative and floral organs. The point of the short, blunt callus is formed by a definite downward projection of the base of the lemma, not by an oblique abscission. This structure is much more pronounced in *Stipa* and *Aristida*. The awn breaks from the lemma by a definite absciss layer.

WETMORE, RALPH H., and ADA C. SMITH, Harvard University, Cambridge, Mass. *Development of the shoot system in Lycopodium.*—A comparative study of the stem apices in nine species of *Lycopodium* shows two major patterns for the apical meristems: (1) a flat-topped apex with erect foliar primordia; (2) a conical apex with lateral foliar primordia. In no species was a single apical initial found. In all species studied, the acropetally developing procambial column reached close to the apex, higher than the highest leaf primordium. In all species cortical tissues were slow in taking form. In the progressive developmental changes giving vascular from procambial tissues there occurred in order: (1) a centrifugal blocking out of the metaxylem and metaphloem pattern in the procambial column; (2) a differentiation of peripherally distributed, somewhat regularly spaced groups of procambial cells into alternate bundles of protoxylem and proto-phloem while stem and leaves were growing actively. At least the protoxylem strands are related to the leaf primordia. In no species investigated did phloem cells ever appear either in the leaf trace or in the leaf lamina; (3) a centripetal differentiation of metaxylem and metaphloem after active growth has slowed down. This method of development is characteristic of both superficial and subterranean rhizomes and upright axes, though differences in pattern may result. The procambial and vascular cylinders seem to be of two portions—a peripheral portion characteristically foliar, and a central cauline portion. It is significant that at times, if not always, the subterranean rhizomes of *L. obscurum* lack leaves except for fleshy scale-like structures with no veins, yet the axis has the same organization.

WHEELER, LOUIS C., Department of Botany, University of Pennsylvania, Philadelphia, Pa. *Dates of publication of Jepson's "Manual."*—W. L. Jepson's "Manual of the Flowering Plants of California" is claimed, on the back of the title-page, to have been issued as six fascicles on various dates during 1923 and 1925. Since the original fascicles are apparently unknown at least in the institutional

libraries of the U. S., verification of the dates of publication is difficult. The earliest notice that has been found which announces any part of the work for sale was published in 1926. In order to reassure ourselves that the extreme rarity of the fascicles is not evidence that they were not published on the dates claimed, we need answers to the following questions relating to and establishing the date(s) of publication of the "Manual." 1. When, where, and how was the work first announced for sale? 2. To whom were the fascicles sent, on or before the claimed dates of publication? 3. When and where was the work first reviewed or noticed? 4. What are the serial numbers of the copyrights covering the fascicles? 5. How does the text of the bound volume differ from that of the fascicles?

WILDE, MARY H., Mount Holyoke College, South Hadley, Mass. *A new interpretation of coniferous cones with special reference to the Podocarpaceae*.—Two species of *Podocarpus* possess similar compound male and female fertile branches. The female fertile branches bear spirally arranged bracts; in the axil of each is a single ovule surrounded by an epimatium (ovuliferous scale), reduced from a secondary, determinate fertile shoot and its appendages. The male fertile branches likewise bear spirally arranged bracts; in the axil of each is a small sessile male cone, a relatively unreduced secondary, determinate fertile shoot. Modifications of the male fertile branch consist in (1) internodal shortening forming primary clusters of cones, (2) loss of all cones except a single terminal one, below which are retained several persistent sterile bracts. Internodal shortening of the secondary and primary vegetative branches results in secondary and tertiary clusters respectively. Ultimately these clusters may be reduced to single cones. Reduction and loss of units have also occurred in the female fertile branches in most species. In a few other species the female fertile branch is organized into a cone. It may be concluded that primitive Coniferae possessed a richly branched habit with similar compound male and female fertile branches; that the simple male cone, a single surviving unit of the primitively compound male fertile branch, is thus homologous with the reduced, axillary secondary units of the female cone; that the great diversity in position of male cones is due to subsequent vegetative branch reduction.

WOODSON, R. E., JR., Missouri Botanical Garden, St. Louis, Mo. *Behind the scenes of a "flora of Panama"*.—Plans for a "Flora of Panama" are discussed, and certain questions raised concerning the scope and format of comprehensive floras in general, particularly with regard to the treatment of exotics. Six general categories of vascular plants are recognized in Panama upon the basis of geographical affinities: (1) Mexican-Central American, (2) Antillean, (3) northern and eastern South American, (4) Andean, (5) Panamerican, (6) Pan-tropic. Various combinations occur. The highland

flora is almost equally Mexican and Andean, but somewhat more the latter; the lowland flora is almost equally Mexican and northern South American (somewhat more of the latter), and a small but distinguishable Antillean element.

WYNNE, FRANCES E., New York Botanical Garden, New York, N. Y. *Methods of reporting plant distribution data*.—In the United States many range extensions are made and reported by amateur rather than professional botanists. Helpful suggestions to amateurs are offered herewith. (1) The title should state the contents as exactly as possible, including mention of new records, new entities, and new combinations. (2) New records should be indicated by asterisks or bold face type. (3) Information about the species concerned should be as complete as possible, including previously known range and length of time established. (4) Specimens should be deposited in as many prominent herbaria as possible, and mention should be made of these. (5) Maps showing distribution are often of value.

ZIMMERMAN, P. W., and HITCHCOCK, A. E., Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y. *Correlation of organs and flowering habit modified by triiodobenzoic acid*.—Triiodobenzoic acid has a formative influence on plants, affecting flowering, growth habits, and correlation of organs. Solutions of the substance were applied to the soil or sprayed on the plants with similar results. One to 10 mg. added to the soil of a four-inch pot were sufficient. As a spray 25 to 500 mg./l. served for the various responses. Under the influence of this hormone-like substance, axillary buds which normally produce leafy shoots were induced to grow flower clusters. The main shoot of the plant also lost the shoot-producing bud and terminated in flower clusters. It was concluded that though triiodobenzoic acid does not cause immediate (within a few hours) cell elongation of test objects, the ultimate results more nearly resemble those of true hormones than the well known indole and naphthalene substances commonly referred to as auxins. The term "formagen" is proposed for substances which have a formative effect on plants involving modification of shape, size, and pattern of organs and flowering habit.

ZIMMERMAN, P. W., and A. E. HITCHCOCK, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y. *Peculiarities in physiological activity of homologs of substituted phenoxyacetic acids*.—Substituted phenoxy compounds have varying degrees of physiological activity as plant growth substances according to the kind (halogen, amino, nitro, or methyl), number, and location on the ring of substituted groups. The activity is further conditioned by the length of side chain and place of attachment to the oxygen. Activity depends upon molecular configuration as a whole rather than upon any one part of the molecule. Substituted phenoxy substances resemble the well known auxins in that they cause cell elongation, epinasty of leaves, and induce adventitious roots; they differ in that they

have a special formative influence on growth organs. The latter effects are exhibited by modification of form and color of leaves, flowers, and fruit. Illustrating peculiarities, 2,4-dichlorophenoxyacetic acid causes both cell elongation and modification of leaves; 2,4-dichlorophenoxy-alpha-propionic acid induces cell elongation but does not modify leaves,

while the beta form is inactive for both responses; 2,4-dichlorophenoxy-alpha-butyric acid is active for cell elongation but does not modify leaves; 2,4-dichlorophenoxymalonic acid is active for both cell elongation and modification of leaves. Other substitutions and homologs show similar as well as other peculiarities.
